On the Mortality among Rats at the Cape Town Docks which Preceded the Present Epidemic of Plague.—Alexander Edington, who made bacteriological investigations of the plague and of the rats at Cape Town, gives the results obtained in detail. He says that although the cultures of the rat microbe are very similar to the somewhat non-characteristic growth of plague, and although the cultures in buttered bouillon give rise to stalactite growth, yet the microscopical form of the bacteria in the body of the rat, together with its pathogenic action, are somewhat at variance with what we know of true plague bacilli. Moreover, he has had numerous opportunities of observing rats affected with bubonic plague in Port Elizabeth; but although he has found an abundance of plague bacilli more or less virulent in action, he has not seen one case in which the rat microbe found in the early mortality at the south arm of the Cape Town docks has reappeared. He must, therefore, until further observations have otherwise convinced him, adhere to his belief that the disease which primarily caused the mortality among the rats at the Cape Town docks was not true bubonic plague, although undoubtedly caused by a variety of the bacillus of hemorrhagic septicæmia.

Münchener med. Wochenschrift, July 16 *and* 23, 1901.

A Crystalline Immunization Product.—H. Buchner and L. Geret describe a reaction occurring when the serum of rabbits that have been prepared by the previous injection of pepton is added to a solution of the same sort of pepton. The fluids are poured into a test-tube so as to form two layers, when after a longer or shorter period of time a precipitate forms at their line of junction and attaches itself to the sides of the tube. This precipitate is made up of minute bodies or "globulites." A similar precipitation takes place if, instead of pepton solution, defibrinated bullock's blood is used to prepare the animal, but the pepton solution used for the second part of the experiment must be beef pepton, as that of other animals does not give the specific reaction. The globulites may be readily formed for study beneath the microscope by placing a drop each of specific serum and pepton solution on a cover glass so that their edges touch, and inverting over a hollow slide. The bodies vary in size from 2 to 35 μ according to the rapidity of formation, are highly refractile, and very resistant to the action of strong acids and alkalies.

The Tenacity of the Scarlatinal Contagium.—F. Lange reports a case which demonstrates the extraordinary longevity of this virus with almost the accuracy of a physiological experiment. One of the inmates of an institution for deaf children contracted scarlatina, was kept overnight in the isolating room, and then sent to a hospital for treatment, whence he returned in 3 weeks and resumed his intercourse with the other children without the occurrence of further cases. The isolating room, after a superficial formalin disinfection, was occupied by a sixteen-year-old girl for 133 days, when a child of nine was allowed to sleep in it for several nights. Twelve days later, this child came down with scarlatina, but the other children were affected. Inasmuch as the inmates of the institution did not come at all into contact with the outside world, the only conclusion possible is that the contagious principle had remained active in the room during the whole period since its former occupancy by the diseased child. The fact that the young girl who afterwards used it came into daily contact with the children without harm is a further proof of the slight risk of a third person's spreading the disease.

Quinic Acid and Gout.—De la Camp has conducted a series of investigations on the value of this agent as a remedy in gout with the result that it seems to offer much that is encouraging to further investigation. Whatever its value, however, the usual dietetic regulations must always be enforced, and the use of carbonated waters is an especially valuable adjunct. Quinic acid does not regularly affect appreciably the uric acid excretion of healthy and gouty individuals on normal diet, but a considerable increase in hippuric acid is always demonstrable. At present it seems that quinic acid is more efficient in decreasing uric acid excretion in those cases in which at the same time a considerable amount of uric-acid-forming food is being taken, or the organism is excreting large amounts of uric acid, as in leukæmia. While the interrelationships of uric and hippuric acids in the human being are very obscure, owing to the difficulty of drawing the proper conclusions from animal and test-tube experiments, the available clinical evidence indicates that quinic acid deserves a place in the therapeutics of gouty diseases.

The Origin and Treatment of Pharyngeal Abscesses.—L. Grünwald says that the commonest form of tonsillar suppuration is the supratonsillar abscess which takes its origin from an infection starting between the pillars of the fauces in the supratonsillar fossa. If opened, as is usually the case, at the site of perforation, the danger of relapse is considerable, while if the incision is made through the infectious region in the supratonsillar fossa this risk is eliminated. True peritonsillar abscess is a great rarity, and usually emanates from dental trouble or foreign bodies. It may be diagnosticated from the foregoing by the fact that as the pterygoids are not implicated, there is no inability to open to the mouth, and the source of the infection may often be traced to a diseased molar. The tonsillar abscess is also rare, and may be opened by a downward puncture through the supratonsillar fossa, though it is better practice to split the tonsil from top to bottom. Acute retronasal suppuration also occurs, and is indicated by the nasal obstruction attending it. The author does not believe in the acute infectious type of pharyngeal abscess described by some authors, but considers that even the ordinary varieties can form toxins enough to cause great prostration, the typhoid state, or even death.

Deutsche med. Wochenschrift, July 11, 18, *and* 25, 1901.

The Nature of Schüller's Carcinoma Parasite.—F. Volcker's article is an account of his attempts to corroborate the findings of Schuller by repeating the experiments described in his book as sufficient to unmask the organism of malignant disease. All of his investigations were fruitless, in spite of the greatest care, till he used bergamot oil as a clearing agent, that contained numerous fragments of disintegrated cork from the stopper, which at once the various forms described by Schuller appeared in great profusion. Further study convinced the author that most of Schüller's parasites were artefacts due to contamination in this way, though one form of small granule still remains unexplained.

The Treatment of Hay Fever.—A. Simon has found sulphate of atropine a satisfactory remedy for the obstinate asthmatic attacks usually associated with hay fever

His patient was a man of thirty-three who for fifteen years had been subject to the disease, which began with rhinitis and subsequently developed also conjunctivitis and asthma, the symptoms usually lasting four weeks annually, and increasing in severity from year to year. The whole therapeutic gamut had been run with but slight relief, when it was found that small doses of atropine by the mouth a short time before the expected asthmatic attacks, sufficed to prevent the occurrence of the paroxysms, and the patient was entirely relieved of this the most troublesome phase of his malady, though the nasal and ocular inflammations were not alleviated.

The Palpation of the Rectum from Without and Its Therapeutic Application.—W. Einstein describes this method of examination, which consists in palpating the left side of the gluteal cleft between the tip of the coccyx and the anus. When the rectum is distended with feces, it may be felt in this situation as a rounded, somewhat nodular mass having about the thickness of the thumb. The identity of this tumor may be established by gentle massage directed toward the anus, when feces will be easily extruded, and the mass disappear. The manipulation lends itself to therapeutic use in two ways; first as a substitute for enemata in cases of chronic constipation, and secondly as massage for the purpose of giving tone to a relaxed rectum. Patients readily learn the technique, and can conveniently apply it when seated upon the closet without the trouble attending the use of the syringe, or any risk of soiling the hand.

A Cured Case of Tetanus.—E. v. Leyden reports the case of a groom who on the third day of his disease received a subdural infusion of 5 c.c. of tetanus antitoxin, which was repeated three days later. Ten c.c. of cerebrospinal fluid were first withdrawn and injected into mice, in order to confirm the diagnosis, with positive results. On the day of the first injection the temperature was 105.5° but on the same day it dropped to 101.8°, and the next was almost flat. This lowering of the temperature the author considers of the greatest importance, and he does not recall a single case in which, before the antitoxin days, the temperature reached 105.4° and the patient lived. After the injections, the patient ran the usual course of the disease, with well-marked trismus, though fluids could be swallowed without difficulty. Chloral was found more useful than opium as a sedative, and the nutrition was carefully kept up. Now, in the fifth week, the patient is practically well, though some stiffness of the legs and a trace of the trismus still remain.

A New Bacillus of Syphilis.—J. de Lille and L. Jullien describe an organism they have obtained from the alexin-free plasma and blister fluid of syphilitics. It is a polymorphous bacillus growing well on ordinary media, and after ten days assuming a granular form which, resown, gives rise again to the original type, but after thirty days remains sterile. The organism is to be found in all patients in the florid stage of syphilis, and with their serum gives an agglutination-reaction which does not occur with the blood of non-luetics. Inoculation into animals produces symptoms comparable to those occurring in man, and the bacillus fixes the alexin of animals inoculated with syphilitic products. Syphilitic subjects do not react to infection with it, and in both animals and man it disappears after death, which perhaps accounts for the fact that no case of infection sustained in performing autopsies on luetic cadavers has ever been recorded.

Transitory Mental Aberrations of Hysterical Nature.—M. Sander reports four such cases that have come under his observation. Three of these were in women, all of the lower class, and the fourth in a military recruit. Each of the women had been subjected to prolonged mental strain concerning her love affairs, which culminated in sudden mental irresponsibility, delusions, and attempts at suicide. This condition lasted for from twelve hours to fourteen days, when it ceased as suddenly as it began. The soldier was a naturally weak individual, who was unable to perform his duties easily, and was therefore subjected to the ridicule of his comrades. This resulted in a degree of mental aberration sufficient, in the author's opinion, to account for the development of a state of acute stupor lasting six days, and then terminating suddenly with entire amnesia of the period of illness. Such conditions are much commoner than is usually thought, and especially suicidal attempts on the part of young women are often explicable on these grounds, *i.e.* as being the result of more or less prolonged mental stress, and having an underlying hysterical basis.

Berliner klinische Wochenschrift, July 8, 15, and 22, 1901.

Paroxysmal Tachycardia.—H. Rose reports an instance of this affection in a man of forty-eight who, from youth up, had been subject to cardiac "crises" lasting from hours or days or weeks at a time. Three such attacks were observed by the author, and consisted in a sudden rise of the heart beats to over 200 in the minute without change in the cardiac dulness or marked irregularities. No dyspnœa or pain, no physical signs of any organic lesion, urine negative. The attacks ceased as suddenly as they had come on, in the one case after a week, and in the other two after a single day. In addition, there were marked gastric disturbance and various nervous manifestations, such as herpes labialis and polyuria. The author considers the affection as a central neurosis, though he is unable to explain the rationale of its development.

Zomotherapy.—C. Frankel and G. Sobernheim publish some investigations made to determine the value of a form of treatment for tuberculosis called zomotherapy, advocated by Richet and Héricourt. These observers found that by feeding dogs with raw meat they were able to prevent the development of artificial tuberculosis in these animals. Dogs fed on ordinary diet succumbed thirty to forty-five days after inoculation with virulent bacilli, while others that had daily received one to three pounds of raw meat were still alive six months after the injections. The authors repeated these experiments on two sets of dogs (ten in all), and on a series of four rats. The animals were divided into pairs, and all the conditions of inoculation, etc., were kept as nearly as possible identical for the two, except that one was kept on mixed diet, while the other received only raw meat. The results were wholly at variance with those of the earlier investigators, for there was no difference in susceptibility of the animals to the disease, and possible sources of error were so carefully excluded that the authors believe the proposed plan of treatment offers but little encouragement.

Alterations in the Multinuclear Leucocytes in Some Infectious Diseases.—H. Hirschfeld describes a change in the staining properties of the granules in the multinuclear neutrophilic leucocytes. This was observed in pneumonia, scarlatina, and phthisis, with high temperatures, also in measles with bronchopneumonia, but not in typhoid fever or uncomplicated measles. In these affections the granules of the multinuclear leucocytes, which ordinarily are neutrophilic, become basophilic, and may be stained with methylene blue or methyl green. Usually most of the cells exhibit this change, but often only a larger or smaller portion take up the basic dye. Observations in the cells of bone marrow which exhibit similar changes under these conditions lead the author to believe that this characteristic is indicative of youth, though this is only a tentative hypothesis. Another morphological change was observed in all infectious diseases accompanied by high temperature, and consisted in the presence of an oval or circular body either at the periphery of the multinuclear neutrophiles or else situated between the edge of the cell and the nucleus. These were to be seen only when methylene blue or eosin-methylene blue was used, and then appeared stained faintly blue. The author was not able to determine whether these bodies were due to nuclear degeneration, or whether they were of the nature of centrosomes.

French Journals.

Contusion of the Abdominal Wall, with Only a Subcutaneous Rupture.—Legnen reports an interesting case of a man who received a severe blow on the abdomen. The aponeurotic layer only was ruptured, without any deeper lesion. There was a slight hernia in consequence, for which the writer performed a radical cure later on. The patient made an uneventful recovery.—*La Presse Médicale*, July 13, 1901.

Permanent Slow Pulse.—A. Halipré gives some interesting observations on this subject, concluding by the description of an old man who had been afflicted for eighteen months by crises in which he suffered from a slow pulse, syncope, and incontinence of urine. The alteration in the vascular system was evident from the state of the cardiac contractions, the hardness of the radials, and the traces of albumen in the urine. One suspects in this patient the existence of nodular arteritis, so frequently seen in advanced age, and the habitual cause of the vertigo of the old, and even of senile epilepsy. Whatever the causal lesion may be, the clinical diagnosis of this syndrome is not open to discussion.—*La Revue Médicale de Normandie*, June 25, 1901.

Intubation and Tracheotomy.—G. Carrière reviews several causes of laryngeal obstruction: Neoplasms, both malignant and benign, phlegmonous laryngitis, cicatricial or congenital malformation of the parts, loss of tonicity of the vocal cords, and muscular constriction. In order to overcome the asphyxia so caused, two operations present themselves: tracheotomy and intubation. The ques-

tion of choice is complex. Intubation offers several advantages over tracheotomy. The laity accepts it with more ease; it does not leave a lasting scar; the following shock is less than that after tracheotomy, the air which reaches the lungs is purer than that through the tracheal cannula; convalescence is shorter; the mortality is less than that observed after tracheotomy. However, a physician who has never seen the operation, but who is familiar with tracheotomy, should never attempt the former; tracheotomy should be chosen if the physician lives far from the patient, and if there can be no trained attendant present; if the child is at the point of death, tracheotomy should be performed at once; it is also indicated in intense glottic oedema. In general, every laryngeal affection accompanied by ulceration ought to be tracheotomized, as well as all permanent laryngeal stenoses. Intubation is indicated in laryngeal paralysis, also in laryngeal phthisis or syphilis if there is no ulceration. In cancer, tracheotomy should be done. The technique of these operations should be acquired by careful practice on the cadaver.—*La Clinique Médicale*, July 15, 1901.

Varicose Tuberculosis of the Anus.—G. Augier and J. Voituriez speak of this variety as a rather rare form of cutaneous tuberculosis. This affection is often mistaken for papillomatous epithelioma, and the two can sometimes be differentiated only by careful histological examination. The following case is cited: The patient was a man aged fifty-three years, ordinarily robust, though rather thin. He had no cough, nor any signs of pulmonary tuberculosis. He had no venereal history. He had, about five months previous to his appearance at the hospital, felt the presence of a small, painless mass, which at first he took for a hemorrhoid. Later he suffered pain on defecation, and crises of constipation occurred. Then came a discharge of pus from the anal region. On examination, there was seen a slightly elevated area at the margin of the anus, irregular, but clearly defined, and of a grayish pink color. It was made up of small elevations about 2 mm. in height, and separated by tiny grooves. About in the center was a deeper groove, pink, and of a cicatricial aspect—evidently the source of the pus. The right side of the sphincter was indurated. The consistence of the mass was rather hard, but it did not possess the characterisitc resistance of true epithelioma. The mass was excised and examined carefully. There were a great number of typical tuberculous nodules, with giant, epithelioid, and embryonic cells. The connective tissue was completely masked by the embryonic elements and the giant cells. This affection appears like tuberculosis of inoculation, and may be observed in individuals presenting no sign of pulmonary tuberculosis.—*Journal des Sciences Médicales de Lille*, July 13, 1901.

American Journal of the Medical Sciences, August, 1901.

Anæsthetics in Heart Disease.—John M. T. Finney quotes from MacLeod the three factors which contribute to the uncertainty of the result in the administration of an anæsthetic: "The special action of the agent employed. The peculiarities or idiosyncrasies of the patient as to susceptibility. The skill with which the agent is administered." From the study of 142 cases, he believes that in the myocardial affections only do anæsthetics exert any markedly bad effects. In valvular disease their influence is very slight, but yet they are appreciable; while in functional disturbances they are insignificant. He is convinced that in every operation the anæsthetist plays almost as important and sometimes a more important part than the operator. The hospitals should possess a thoroughly competent corps of anæsthetists, and the medical schools should offer a complete course of instruction in the proper methods of administration of these agents.

Cardiac Accidents After Anæsthetization.—Alfred Stengel concludes that it is always difficult to determine whether cardiac disturbance after operation is due to the anæsthetic or to the operation. In many cases of cardiac disease the use of ether is temporarily beneficial to the cardiac condition. There may, however, be secondary unfavorable effects. Such accidents as basal pneumonia, gastroduodenal disturbances, and especially embolism, are the results of a weakened condition of the heart, and may be due to anæsthetization or to the shock of the operation. The writer believes rather that the unfavorable results of anæsthetics are due to the disturbance of the nervous mechanism or to the muscular automaticity, than to organic changes in the myocardium, endocardium, or pericardium.

Pre-existing Heart Disease in Reference to Surgical Operations.—William J. Mayo believes that the knowledge of cardiac insufficiency in a patient robs it of much of its danger. Valvular disease is generally well compensated between the ages of ten and forty years. The condition with [illegible] fear [illegible] carditis. In the records of operations which he has studied, over one per cent of the patients have had some form of heart lesion existing before the operation.

The Safest Anæsthetic to Use in Organic Diseases of the Heart and Vessels.—H. A. Hare declares that very few people even with grave cardiac and vascular diseases die as a direct effect of the anæsthetic. Indeed, statistics show that very few people with cardiac disease die from this cause. A greater number of those afflicted with heart disease die at stool or in going up stairs, than from the effects of anæsthetics. Anæsthetics when skilfully given are attended rather by favorable than by unfavorable results. The shock of the operation is to blame for the majority of accidents occurring during the administration of an anæsthetic, rather than this agent itself.

Some Conditions other than Aortic Aneurism which Determine the Occurrence of the Tracheal Tug.—Henry Sewall, from his study of the tracheal tug, does not believe it to be pathognomonic of aortic aneurism. He concludes that a tracheal tug quite palpable in character is, in the majority of cases, associated with and dependent upon adhesions of the left pleura. Diminished extensibility of the lung tends to produce the same phenomenon, and the tug is most pronounced when the conditions are combined. Also in the normal individual, descent of the heart with inspiratory movement of the diaphragm may so press the aortic arch upon the left bronchus as to impart to the trachea the aortic pulse, recognizable at the larynx as a palpable tug of greater or less distinctness.

Primary Sarcoma of the Thyroid Gland.—August Jerome Lartigau concludes that primary sarcoma of the thyroid gland is rare, but probably of more common occurrence than statistics show. It is less frequent than primary carcinoma of the thyroid gland. It is commonly associated with goitre. Cases developing in persons between forty and sixty years of age show a higher percentage of previous goitre than those in younger individuals. Goitre associated with sarcoma of the thyroid is more common in women than in men. Sarcoma of the thyroid occurs oftener in late than in early life, the greatest age frequency being between forty and sixty. Sex is probably an unimportant element. The primary tumor most frequently originates in the right lobe of the thyroid body. This seems to be more frequent in men than in women. The clinical course of the disease is usually relatively acute. Involvement by pressure or new growth of the trachea or larynx is common. Metastasis occurs through blood or lymph channels, or both. Round and spindle- or mixed-celled sarcomata are most common. Angiosarcomata are not rare.

The Edinburgh Medical Journal, August, 1901.

Some Notes on Alcohol in Its Medical and Scientific Aspect.—G. Sims Woodhead sums up his opinion of alcohol in the following words: It is a narcotic poison, of which the pernicious effects are to be seen at all times and on every hand. It is a drug, which under certain conditions may be valuable, but it is a dangerous medicament in the hands of any one but a physician, and even in the hands of the physician or surgeon its exhibition is attended with dangers that attach to the prescription of no other substance in the pharmacopœia; these dangers are not moral only, but physical dangers, resulting from the action of alcohol on the tissues generally, but especially on those of the nerve centres. Its food value under ordinary conditions is practically nil, and, put in the most advantageous light, can only be temporary, and then of an extraordinarily slight and wasteful character.

Reduplication of the Second Sound of the Heart.—C. C. Gibbes considers that reduplication of the second sound is present when the aortic and pulmonic portions of it are sufficiently asynchronous to permit of both being heard, the presence of an interval being an accident, not a necessity. Authorities, as a rule, agree that this reduplication is due to asynchronism of the aortic and pulmonary portions of the second sound, and the author holds that the side of the heart which has to cope with the greatest amount of abnormal intraarterial pressure takes the longest time in getting up steam to overcome the said pressure and open the semilunar valves, it therefore begins its contraction before the other ventricle. The following points have a special bearing on the relative position of the pulmonary and aortic second sounds: (1) The point of maximum intensity of the first portion is, as a rule, in the pulmonary area. (2) The intensity of the second portion is greater in the aortic than in the pulmonary area. (3) There was increased intensity of the second portion to the left of the apex in the cases referred to by the writer.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixty-ninth Annual Meeting, Held at Cheltenham July 30, 31, August 1 and 2, 1901.

(Special Report to the MEDICAL RECORD.)

THE meeting opened according to programme on Tuesday, July 30, at Cheltenham, under the presidency of Dr. G. B. FERGUSON, Senior Surgeon to the Cheltenham Hospital. This was the second visit of the association to Cheltenham. The first was sixty-four years ago, when there were only about 1,000 members.

Following the custom of recent years, there was a church service on Tuesday morning. This was held at St. Matthew's Church, and the sermon was preached by Dean Spence, who dwelt on the changes effected in the works and ways of men by the religion of Jesus Christ, and particularly those changes with which medical men are most in contact. First of these is the new aspect of death as the result of life on earth—dissolution becoming no longer a terror or a speculation, but the gateway into life, into "the garden of the blessed." The glowing conviction of this truth, which made men enamoured of death and martyrdom, paled when the Roman world adopted Christianity *en masse*; but if anything is a foregleam of the kingdom of heaven, it is the brotherhood of charity of the modern Christian world. These results are more the fruit of Christ's teaching. In the long catalogue of these results the heading of one of the chapters of changes stood out in letters of gold. Its development was mainly due to the self-denying labors of the great profession represented in that gathering. Hospitals, unknown to the Pagan world, appeared in the first century of the Church's triumph—a Roman lady, Fabiola, having founded the first in Rome. Were he addressing any other congregation, he might dwell upon the services rendered by physicians and surgeons to this mighty outcome of Christian influence—the hospital and all the blessed services that surround it. Had he to live his own life again he would like to throw in his lot with them, who, in truth, mostly live the life we Christians say we love, who follow closest of all in the footsteps of Him known as God, Redeemer, Friend—the Great Physician, who loves us well, even unto death.

After the sermon an offertory was taken on behalf of the Royal Benevolent Medical College and the British Medical Benevolent Fund, the national anthem was sung, and the service ended with voluntaries from the Hallelujah Chorus and Hollins' overture in C minor.

For those members who arrived in time there was a pleasant prelude provided by an "at home" given in the Winter Garden on Monday night by the Museum Committee. There were assembled many of the local profession, the guarantors and subscribers of the reception fund, and the exhibition was formally opened by the Mayor. This exhibition contains no less than 112 stands, and 3,000 square feet of tables were covered with the display. It was said that this year's exhibition surpassed all previous ones. After the Mayor had declared it open, there were calls for Dr. G. A. Peake (the indefatigable Secretary of the Museum Committee), and on his appearance there was a buzz of expectancy, but he continued his oratory to the announcement that refreshments were waiting in the marquees to be consumed, a statement that elicited much laughter and applause, as most of the company filed out into the gardens, where justice was done to the waiting refreshments, and the time whiled away till towards midnight. There was a rumor during the time that a serious accident had occurred, and it proved afterwards that on a trial trip of the new electric train a car had been overturned and two workmen killed. Dr. Norman Walker, on returning from the "at home," met with a bicycle accident and suffered a dislocation of the clavicle.

GENERAL SESSIONS.

First Day—Tuesday, July 30.

This took place on Tuesday afternoon. The chair was taken by Dr. ELLISTON, the retiring President, who reviewed his term of office and remarked that the association had made satisfactory progress. He then made way for the President-elect, Dr. Ferguson, who, having been inducted into the chair, referred to the coincidence that this second visit to Cheltenham of the association was at the beginning of a new reign and that, on the first visit, an address of congratulation was voted to the young Queen, Victoria, who had just ascended the throne. As a natural corollary he proposed a similar address of congratulation to the King, which was seconded by Dr. Roberts Thomson and carried by the members rising. On the motion of Dr. Beverley, seconded by Mr. V. Horsley, a vote of thanks was heartily accorded to the retiring President.

The President then moved and Mr. Parkinson seconded a vote of thanks to the Rt. Hon. W. H. Long for his strenuous and persistent efforts to stamp out hydrophobia. This was carried.

The President of the Council then presented the annual report in which it was stated that the number of members last year was 18,382. During the year 1,010 members had been elected, 238 had died, and 752 resigned. The revenue last year was £43,419, the expenditure £38,043, including £500 written off for depreciation of plant and other losses. He moved the adoption of the report, which was seconded by Mr. A. Clarke.

Dr. HADDEN moved an amendment respecting the Scientific Grants Committee, but this was passed on to the report of that committee. Dr Brierley criticised the vast amount spent on editorial work, which was above £5,500, while less than one thousand went for science. He asked for further information on this subject. Mr. Clarke offered some explanations of the expenditure on the *Journal* but this only elicited further criticisms and brought up the editor. He stated the principles on which he acted, and mentioned among other expenses the valuable articles on surgical work in the South African war, and argued that such outlay maintained the reputation of their *Journal*. The report was adopted.

On the report of the Scientific Grants Committee, Dr. Hadden's amendment was taken as in order. He moved that the committee be requested to give prizes for original research in specified subjects—such *e. g.* as metabolism—and argued that this would be far more likely to promote scientific progress than the plan at present pursued and in which the money was squandered. He was seconded by Dr. Nelson Hardy.

Mr. BUTLIN deprecated tying the hands of the committee, who were sure to consider any suggestions made. He looked forward to a time when they should have laboratories of their own and have researches made under their own direction. The amendment was defeated by a large majority, and the report was adopted.

Dr SARAT K. MULLICK took an opportunity of again ventilating his views respecting the Indian service. He protested against the report of the Indian Military Medical Services Sub-Committee, and held to his original statements against the services. The committee had given him three months to prepare his evidence, and he was ready with it within that time; but they had already issued their report. He moved that the report be referred back. Mr. George Brown seconded. Surgeon-General Harvey contended that there was not a shred of evidence for the allegations made by Dr. Mullick. He had had two years in which to substantiate his charges; but had not done so. The report was eventually adopted by a narrow majority (44 against 38); and the meeting, by a slightly larger majority, refused to expunge the implied

censure on Dr. S. K. Mullick, who expressed regret that bad feeling had been excited by his simple wish to have an inquiry into Indian grievances.

Presidential Address.—The adjourned general meeting was held in the evening, when a large audience assembled to hear the address by the President, Dr GEORGE BAGOT FERGUSON. The orator took for the title of his address, "Scientific Research: the Indispensable Basis of all Medical and Material Progress." His first duty was, he said, to welcome his hearers to Cheltenham, which had not been visited by the association since 1837. In the year of the Queen's accession, when the fifth annual meeting was held, the association had only 940 members; now it was a great and powerful body numbering 10,000, and including thirty branches in the British Colonies and in India. Having described Cheltenham's many advantages as a health resort, and the virtues of its mineral springs, he expressed regret that they had lately been neglected by those who could afford to visit the Continent, and he assured gastric and hepatic sufferers that they would find the Cheltenham waters still as efficacious as the very best springs of Germany. Turning to the foundations of medicine, he said Terence's sentence, "Homo sum, humani nihil a me alienum puto," might well be taken as descriptive of the modern practitioner of medicine. There was much, no doubt, repulsive to them at first in their professional education, but the cheering thought of doing service to their common humanity removed the feeling of abhorrence that would otherwise have overcome them. Anatomy was the indispensable basis of medicine and surgery, and the younger members of the profession should be careful to dissect whenever they had the opportunity. Dividing diseases into anatomical, physiological, and parasitic, he traced the advances made by medical science in the last century. Speaking of treatment by bleeding, he said this was formerly overdone, but the pendulum had now swung too far in the opposite direction, and lives were lost for want of it. He had himself seen desperate cases of pulmonary obstruction in which he had advised it; but friends objected, and the patient died. On the other hand, there had been remarkable cases of the recovery from epilepsy, puerperal convulsions, and apparently hopeless pneumonia after free bleeding. Pondering over medicine as it stood today, the main fact that struck him about it was how much more it owed to the biologists and to the men of pure science than to the so-called practical men. The practical man was indispensable, but he was not, like the great biologists, a high priest of the Arcana of Nature. The cell theory, for example, lay at the very foundation of modern medicine, and this theory originated entirely with the biologists. Speaking of other great discoveries of scientific investigators, he touched on bacteriology, the Röntgen rays, antitoxins, animal extracts, the investigation of malaria, ophthalmology, and the work of the scientific chemists—Courtois, who gave us iodine in 1811; Balard, who gave us bromine in 1826; Serullas, who discovered iodoform in 1822; Soubeiran, who discovered chloroform in 1831; Liebig, who discovered chloral in 1832, and Neimann, who gave us cocaine in 1860. Not one of these was a practitioner, nor, he was sorry to say, a Briton. He was afraid that Great Britain and Ireland would not play a worthy part in the advance of pure science till some improvement was made in their educational system. On the Continent, he had been struck with the thoroughness and scientific spirit everywhere manifested; very different from the anti-scientific spirit in this country. This might be remedied by better education of the young. The cost of an adequate system would be as nothing in proportion to the gain: and a Faraday, a Koch, or a Pasteur would be a cheap purchase at a million. In conclusion, the President urged members to be jealous of the dignity of their profession, and to aspire for the very best in each department of practice.

Second Day—Wednesday, July 31

This extremely important meeting was looked forward to with unusual expectation, as its chief business was the reorganization of the association. A committee had prepared a new constitution, which had been circulated and discussed in the *Journal* for months, and there were thus elicited many differences of opinion as to the proposals.

Mr. E. Owen, chairman of the Constitution Committee, moved the adoption of the report as conciliatory in form and opening the way for such further reforms as might be found desirable. He did not advise throwing the association into the melting pot in the hope of getting a Royal Charter. Mr. V. Horsley seconded, and the President put the resolution and pronounced it carried almost unanimously.

Mr. Whittaker, of Great Yarmouth, moved "That the principle of the report be adopted." He thought it would avoid the distinction of members attached and unattached to branches and remove local prejudices. It would also substitute a distinctly elective body for what is very much of a chance assembly. Mr. Verrall, of Brighton, seconded, and the resolution was carried on the understanding that the clauses of the report should be considered individually. Long discussions followed; various amendments were put forward; some were accepted, others negatived, widely varying opinions were expressed, and the discussions had at length to be adjourned. It was rather wearisome, and may not much interest persons who are not members.

The association accepted an invitation to Manchester for 1902, and appointed Mr. Walter Whitehead, President-elect.

In the afternoon following this meeting, a garden party was given by the Mayor and Mayoress of Cheltenham to the members of the association and their ladies.

Address in Medicine.—Dr. JAMES F GOODHART, at the evening session in Princess Hall, delivered this address, under the title "Friends in Council," in which he took up the relation of the patient to the practitioner in its widest signification. With all the accumulated knowledge of the medical profession, he said, there is much about the mechanism of the human economy and the relation of drugs to disease that is not only not known, but probably never will be known. The physician is hampered because the patient wants to know too much and is better satisfied to have his ailment named at once and wrongly so by an incompetent man than he is to trust himself to the care of a man who knows his own limitations, but who is capable of scientific investigation of a condition, of arriving at an accurate conclusion, and of finding a cure or at least an amelioration for the trouble. The people of the present time were morbidly sensitive, and sought the physician and the surgeon unnecessarily, and there was a tendency for the profession to be morbidly conscientious; there were many departures from normal in the human mechanism still consistent with longevity and a fair degree of health. The public had the dangerous "little knowledge" gleaned from advertisers and from the unguarded expression of opinions by physicians, too often incompetent ones, and often lost sight of the personal equation in their constant demand for a system of medication.

So far as doctors were concerned there was a morbid readiness on their part to detect disease, and there existed a risk that they too little appreciated how good a state of health was compatible with numberless slight and sometimes even considerable departures from normal. Doctors tended to make their standard too severe for practical purposes. He took for example the heart. Over and over again a heart was said to be strained, or weak, or dilated, or even diseased from a want of sound appreciation of what was to be considered health, not for the general case, but the particular. He hated the term "weak heart." It confined or threw useless

upon society many an otherwise useful life. Hearts were either diseased or healthy. They were all the better for plenty of work. Many a one who coddled a weak heart died of disease which an indolent habit had produced. Respecting drugs, the doctor said they were given often as an experiment. The public were particularly sensitive and ill-informed on this matter. It was often said as a matter of prejudice against hospitals that the patients were made the subjects of experiment. So they were, but it happened not only in the hospital. Each new patient was more or less a case for experiment—the king sitting upon the throne as well as the poorest subject. It was by experiment that the value of drugs was established and new powers gained over disease. The cure of disease was always the fundamental object. He would not for a moment even seem to discountenance new remedies. What he would discountenance was giving drugs by rule of thumb. The open-air treatment of consumption of which we heard so much nowadays was bidding fair to come under the baneful influence of routine. The "new treatment," what did the consumptive and his friend see in this? He saw a residence for a few months in a home, and a cure at the end of it. Was this what he had any chance of obtaining? Certainly not, and in proportion to the exaggerated hope would come the bitterness of disappointment to him and the discredit to the doctors. The benefit to be obtained in these sanatoria was that there would be learned a habit of life, plenty of good food and plenty of fresh air, and, having learned his lesson, the tuberculous man would need to practise it all the rest of his life. There was no cure in this treatment, as the sick man understood cure. Although it was true that there was no disease more often arrested than phthisis, it was equally true there was no disease that had a more inveterate tendency to relapse, and he feared that in the balance relapse had the better of arrest. Therefore, if the open-air treatment was to take its real place, and be of any abiding value, the principles of the sanatorium must be introduced into the home. Antiseptics in lung disease had had a long day, tempered by a momentary lull when it was proposed we should be converted into gasometers for that storage of sulphureted hydrogen which was to cure consumption. He mentioned this only to show how much we needed to keep our imaginations in check in thinking of the cure of disease.

Third Day—Thursday, August 1.

This day began with the annual breakfast provided by the National Temperance League. The Rev. W. Flecker, head master of the Dean Close Memorial School, presided. He remarked that many clergymen were total abstainers, but people were apt to regard that as a matter of business, and so they had less influence against the consumption of alcohol than doctors who were abstainers.

Mr. Eccles observed that few doctors now advised the use of alcohol indiscriminately. They prescribed it, if at all, in regular medicinal doses like other dangerous drugs.

Dr. Ridge, Secretary of the Medical Temperance Association, said it numbered 500 members and nearly 500 student associates.

This day also the adjourned discussion on the constitution had to be continued. It was carried on in the same way, all opinions being freely expressed and amendments fully considered. Eventually the adoption of the report was carried with only minor alterations, and the association will enter on its new career.

Address in Surgery.—Sir WILLIAM THOMSON took for the subject of his address, "Some Surgical Lessons from the Campaign in South Africa." He said that the large proportion of wounded who recovered was totally unexpected, and was due partly to the character of the bullets employed and partly to early application of the first dressing; the high temperature and very dry atmosphere were also favorable. The high-velocity bullet striking a bone at short range made a much comminuted fracture; the destructive effects lessened as the range was increased, and the velocity of the bullet consequently diminished; therefore when a bone was broken by a bullet and there was no other lesion but the track through unimportant soft parts, the indication was to apply an antiseptic dressing, secure immobility, and keep the patient at rest till more deliberate attention could be secured. In no war had the number of amputations been so few, the number of limbs saved so many, or the operation-mortality so small. Excisions were rare, and amputations were done on the field only when vital parts were involved or when great destruction had been caused by a shell. The treatment of penetrating abdominal wounds was unsatisfactory whether operated on or not. The orator thought that a man with an abdominal perforation by a small-bore bullet had a better chance of life without operation, considering the circumstances under which laparotomy on the field must be performed. He did not think the practice of searching for and removing bullets under ordinary circumstances was justifiable.

The Stewart Prize was presented to Dr. Patrick Manson for his researches on tropical diseases, particularly tracing the life history of the malarial parasite.

Mr. GEORGE BROWN brought forward a resolution against the Midwifery Bill or any legislation which will form a separate class of practitioners. He condemned the conduct of the Obstetrical Society in sending out women with three months' training. After some discussion the motion was withdrawn.

Dr. DOYEN, of Paris, gave an exhibition of instruments and of operations illustrated by the cinematograph. At 7 P. M. the public dinner was held, followed by the ladies' reception.

Fourth Day—Friday, August 2.

The concluding general meeting was chiefly occupied with votes of thanks to various persons who had helped to make the meeting a success and some other rather formal business. Afterward there was the excursion to Gloucester for those who desired a little change from the more serious work of the sections, and to close up this serious work was a soirée and dancing

SECTION OF SURGERY.

First Day—Wednesday, July 31.

Renal Tension.—The President, Mr. REGINALD HARRISON, opened the proceedings of the section with a paper on "Renal Tension, and its Treatment by Surgical Means." Mr. Harrison's attention was first directed to the subject by the good results following operations undertaken for the relief of symptoms pointing to calculus or other removable cause where no such condition was discovered. The descriptions given by medical writers of the post-mortem appearances of kidneys which had been the subjects of nephritis were highly suggestive of the probable value of mechanical assistance toward recovery. High tension in an inflamed kidney leads, in addition to hemorrhage and exudation, to a slow extravasation of urine into the tissue, which is highly destructive. Analogies may be found in the evil effects of high tension in the eye and in the testicle. Six cases were narrated, one operated on for supposed pyonephrosis, two for supposed stone, two for hæmaturia and other symptoms following injury, and one for cystic disease. In all of them nephrotomy was followed by recovery; in the case of cystic disease, drainage was continued for thirteen months. Mr. Harrison did not advocate nephrotomy for the ordinary cases of acute nephritis, but for those which are passing on to the subacute and chronic stages and for what he termed the malignant type. The operation consists of a limited incision through the renal capsule along the con-

vex border. Drainage is carried out for a variable period thereafter.

Mr. W. D. SPANTON could quite appreciate how impossible it is for a congested kidney to relieve itself in any other way than by leading to hemorrhage or some destruction of its delicate tissues by compression. He narrated two cases, showing a good result following simple nephrectomy; one a case of chronic nephritis with hæmaturia, the other a case of injury during gymnastics and aggravated by a kick. In neither was any definite lesion found on operation; in both the hæmaturia and other symptoms disappeared.

Dr. WARD COUSINS expressed the opinion that those cases in which the procedure was likely to be of most benefit were the cases in which the kidney had been healthy up to the commencement of the attack. He had had the same experience as Mr. Harrison in regard to operating for supposed stone with good result where no stone was found. In cases of renal disease associated with bladder trouble he did not think the proceeding likely to be of value.

Mr. BARLING believed in the efficacy of wet cupping in the loins. He considered that cases of injury to one kidney were those most likely to be benefited by incision as recommended.

Mr. R. C. CHICKEN did not think a premeditated nephrotomy simply for the relief of tension was justifiable. Incision into the kidney did not permit of clearing out of clots.

Sir WILLIAM MCCORMACK congratulated Mr. Harrison on his paper.

Renal Calculus.—Mr. JONATHAN HUTCHINSON, Jr., then read a paper with this title. He advocated that method of removing calculi which caused least disturbance to the kidney and its surroundings. Skiagraphy he had found of great value as an aid in the certainty of removing all stones, of exactly localizing the stones, and of demonstrating small stone. The radiograph defines the position of the stone with great accuracy. It is not uncommon to find pain referred to the side opposite to that on which the stone is; in such cases skiagraphy will prevent mistakes.

The PRESIDENT enquired as to the possibility of coloring calculi with methylene blue in order to increase the density of the shadow.

Mr. RUTHERFORD MORRISON thought that skiagraphy had not yet reached the point of perfection where one could say with certainty that no stone was present. He advocated incision through the renal pelvis for the removal of stones.

Dilatation of the Stomach.—Dr. HERBERT BRAMWELL read notes of a case of extreme gastric dilatation. This was secondary to peritoneal bands arising in connection with a movable right kidney, which caused duodenal constriction and pyloric stenosis. The case was illustrated by a card specimen.

Operative Treatment of Femoral Hernia.—Mr. R. H. PARRY read a paper on this subject. He described and demonstrated by a model a method of closing the ring from above, which he had devised. He had operated on fifteen cases by this method with good results. Details of the method were discussed by Mr. JORDAN LLOYD and Mr. MCADAM ECCLES.

Prevention of Shock.—Mr. W. H. BROWN read a note on the prevention of shock during prolonged operation. He drew attention to the advantages of continuous transfusion during the course of the operation in cases in which much hemorrhage was anticipated.

Mr. JESSOP supported the views of the writer as to the great value of transfusion in shock. He was in the habit of using large quantities of fluid, as much as five pints, and he also relied on strychnine.

Second Day—Thursday, August 1.

Ulcer of the Stomach and Duodenum.—Mr. GILBERT BARLING opened the discussion on this subject. He said he would exclude perforation of gastric ulcer and cancer of the stomach; he proceeded to consider the mortality of gastric and duodenal ulcer and the conditions calling for operation. These were (*a*) hemorrhage, whether acute or recurrent; (*b*) long-continued pain, vomiting, loss of weight, and repeated disability for work; (*c*) pyloric stenosis with dilatation and gastric stasis, (*d*) adhesions causing stenosis or pain. The methods by which surgery offers relief or cure were next considered, viz., pylorodiosis, pyloroplasty, gastrolysis, gastrojejunostomy, either anterior or posterior, by suture or apparatus, or by simple or special approximation.

In acute fulminating hemorrhage not much success could be expected; in recurrent hemorrhage either gastrojejunostomy or direct treatment of the ulcer could be tried. The cases due to adhesions and stenosis were difficult. He did not favor Loreta's operation on account of the danger of rupturing the coats. Pyloroplasty was perhaps the best plan except when there was great thickening of the pylorus and numerous adhesions. But it was not applicable for the relief of hemorrhage or of pain. As to the simple separation of adhesions, it was at best an incomplete procedure. Mr. Barling had only done anterior gastrojejunostomy once. He used Murphy's button, but has returned to suture. The mortality he estimated at about twenty per cent., its chief cause being delay in operating.

Mr. HEATON estimated the mortality at less than half Mr. Barling's figure. He favored the button. The most favorable cases were those operated on for pain and vomiting.

Mr. BIDWELL recommended Loreta's operation when pyloric stenosis depended mostly on hypertrophy of the muscular coat. He reported last year four cases of pyloroplasty; three of these had since remained well, the fourth had been operated on again for adhesions. In gastrojejunostomy he preferred suture to the anterior operation.

Mr. SINCLAIR WHITE thought pyloroplasty applicable in a few cases, but gastrojejunostomy was much more frequently of service.

Mr. C. A. MORTON related a successful case of gastrojejunostomy for gastric ulcer of seven years' duration.

Mr. RUTHERFORD MORRISON had performed pyloroplasty twenty-two times without a death. Adhesions he held to be always secondary, and he opened the stomach when they were present. Gastrojejunostomy had given him unsatisfactory results, regurgitation being the chief difficulty.

Mr. PAUL BUSH had found the posterior operation much more difficult than the anterior.

Mr. PARRY related two successful cases of pyloroplasty in which he had removed a considerable amount of cicatricial and hypertrophied tissue.

Dr. FERGUSON related a successful case. He operated three hours after perforation of a gastric ulcer which he sutured, then sponged the peritoneal cavity and closed the abdomen.

Mr. MURPHY advocated early operation and Mr. D'ARCY POWER thought that the number of such cases was on the increase.

Mr. J. RUTHERFOD MORRISON then read a paper giving the after-history of a series of cases of gastric ulcer and pyloric stenosis treated by pyloroplasty. The first eleven were fully reported (*Lancet*, February 26, 1898). One he had been unable to trace. The sex, age, date of operation, and results follow after the number of the case in the table: Case 1. Female, 48, October, 1894; is perfectly well, has no symptoms, can take ordinary food, has gained 76 pounds. 2. F., 37, October, 1895; is very well, has no symptoms, takes ordinary food, gained 6 pounds. 3. M., 31, January, 1896; is perfectly well, has no symptoms, takes ordinary food, gained 42 pounds. 4. F., 59, April, 1896; died six months after from malignant tumor of the pylorus; the symptoms improved for a time. 5. M., 32, August, 1896; his father reports "he is very well and is out in Africa with the army." 6. M.,

25, October, 1896; is very well, has no symptoms, takes ordinary food, and has gained 41 pounds. 7. M., 56, December, 1896; died of phthisis April, 1899; his physician reports that "up to his death he had no trouble with his stomach, he took ordinary food, he gained weight up till the time the lung condition appeared." 8. M., 42, March, 1897; is in good health, at times has some return of his old symptoms, gained 12 pounds. At operation no lesion of the pylorus was found (spasmodic stricture?). 9. M., 38, March, 1897; very well, takes ordinary food, is working as a miner, gained 38 pounds. 10. F., 56, September, 1897; very well, takes ordinary food, gained 22 pounds. 11. F., 39, September, 1897; cannot be found. 12. F., 40, November, 1897; very well, no symptoms, takes ordinary food, gained 27 pounds. 13. M., 23, June, 1898; very well, no symptoms, takes ordinary food, gained 20 pounds. 14. M., 41, July, 1898; is very well, no symptoms, takes ordinary food, gained 42 pounds. 15. F., 36, July, 1898; good health, can take ordinary food, occasionally has a little indigestion, gained 33 pounds. 16. F., 30, November, 1898, health much improved, takes ordinary food with care, gained 13 pounds. 17. M., 46, November, 1898; very well, no symptoms, takes ordinary food, gained 34 pounds. 18. F., 21, January, 1899; very well, takes ordinary food, gained 35 pounds. 19. F., 45, March, 1899; in poor health, takes food sparingly, mostly slops, often has indigestion (insufficient notes). 20. F., 36, May, 1899; very well, no symptoms, can take ordinary food, has gained 28 pounds.

The Treatment of Cancer of the Breast by Oöphorectomy and Thyroid Extract.—Dr. George Thos. Beatson read a paper with this title, giving a short outline of a case operated on within the last year, in which the beneficial effects of the oophorectomy, combined with the administration of thyroid extract, were well shown. Within a period of six months a large cancerous mamma in a patient aged forty-four had entirely atrophied, and the extensive glandular enlargement which was also present had completely disappeared. After showing that other surgeons have furnished corroborative evidence of what Mr Watson Cheyne has called the "striking" control exercised over the course of carcinoma of the female breast by oophorectomy and the administration of thyroid extract, consideration was given to the possible explanation of the results observed. As bearing on this point, reference was made to that interesting group of cases in which what may be termed a spontaneous disappearance or quiescence of mammary carcinoma has been observed. No very satisfactory explanation of these cases has been furnished so far, but it was just possible that some ovarian influence had come into play as the factor in the occurrence. Apart altogether from the therapeutic value of oophorectomy and thyroid extract in cancer of the breast, the speaker said, the results obtained by it must be regarded as valuable in connection with the etiology of carcinoma, at any rate of carcinoma of the female mammary gland if not generally. They would seem to furnish strong evidence against the parasitic theory of the disease. Dr. Beatson dealt with the cases suitable for the operation and discussed the advisability of combining it with the administration of thyroid extract in moderate doses, experiments having shown that large doses have no specially beneficial effect. Lastly, he raised the very important point as to whether sufficient evidence has been furnished to justify the adoption of oophorectomy as a primary method of treatment in the early stages of mammary carcinoma, either by itself or combined with the present recognized operation.

Mr Barling thought such time had not arrived. It had not been shown that the ovaries had any specific effect on cancer.

Mr. Chicken combined this procedure with as complete removal as possible. Mr. Eccles regretted the uncertainty of results. Mr. H. Styles supported Dr. Beatson's view.

Mr. Morrison mentioned two cases of simple removal, in which there was no recurrence for twenty-five years in the one, and six in the other. These results scarcely favored Dr. Beatson's view.

Section of Obstetrics and Gynecology.

First Day—Wednesday, July 31.

President's Address.—Dr. J. W. Byers, Professor of Midwifery in Queens College, Belfast, opened the Section with an address in which he reviewed the progress of obstetrics and gynecology during the last century.

The Causation, Prevention, and Treatment of Miscarriage.—Dr. Peter Horrocks of Guys Hospital, London, in opening the discussion on this subject, said that he used abortion and miscarriage as synonymous words to signify the expulsion of the fœtus from the uterus before the period of viability, but for the purpose of this paper he preferred the word miscarriage, as abortion was the term always used in the law, and in the mind of the public it was associated with criminal proceedings.

The proportion of abortions to labors at term had been very variously estimated; he would place it at about 1 to 5. Primparæ were less liable to abortion than multiparous women. In all probability fertilization occurred sometimes in the tube and sometimes in the uterine cavity. In some cases, owing to a diseased condition of the endometrium, the villi of the fertilized ovum could not secure an attachment to the uterine wall, and the ovum was carried away in the stream of the next menstrual flow; in these cases there was no arrest of menstruation and he would call them cases of "menstrual abortion," though the occurrence of this had not been absolutely proved. When a period had been missed the occurrence of abortion was attended by more bleeding, and a very large proportion of abortions occurring after the missing of only one period were of criminal origin. All abortions depended on a premature separation of chorionic attachment to uterine wall.

The causes of abortion were: (1) Criminal, by curette, sound, etc. (2) Accidental, by strain, coughing, operations on the pelvic organs, vaginal walls, rectum, perineum, etc., or the shock incidental to the extraction of teeth. (3) Diseases of neighboring parts, such as fibroid tumors (he thought this was a frequent cause of repeated abortions, generally coming on about the third or fourth month), para- or peri-metritis, diseases of the Fallopian tubes, hæmatocele, or diseases of the rectum. (4) Artificially induced abortion for legitimate purposes. (5) Fœtal causes were syphilis (this was nearly always of paternal origin; a man who was the subject of syphilis should not marry for two years after he had been free from symptoms; syphilis caused abortion at any period of pregnancy usually in later months of non-viability), vesicular mole, scanty liquor amnii, deficient vitality from the father, or cord too short, containing knots, etc. (6) General conditions of the mother such as puerperal eclampsia, zymotic fevers, etc. Voluntary starvation sometimes practised with the intention of bringing on abortion cannot do so.

Treatment.—In the prevention of abortion he urged the avoidance of violent exertion, excessive coitus, shocks, frights; he thought dogs were very dangerous in this respect owing to their suddenly jumping on the woman.

Pessaries were not to be worn after the fourth month, and no vaginal syringing should be permitted.

Ovarian tumors could be removed, and retroflexion of the uterus could be put right by the knee-elbow position and a temporary pessary. Tight lacing must be avoided, also strong purgatives, particularly those containing aloes. Excessive constipation was also dangerous. Enemata must be used cautiously, when neces-

sary—oil was the best, and turpentine must be avoided. Quinine must be avoided. If syphilis was the suspected cause both man and woman should be treated beforehand and the woman should take mercury in small doses throughout pregnancy. Over-suckling must be avoided and a child should be weaned at ten months. Extraction of teeth should be avoided, but if that was necessary an anæsthetic should be given.

In the treatment of threatened abortion, if any bleeding occurs the woman should be examined. If the os was not patent, and the pains were not violent, the patient shall be kept strictly in bed—not even allowed to get up for micturition. Opium should be given, and viburnum prunifolium was useful. When the hemorrhage was severe and repeated the right plan was to empty the uterus. When the os was dilated the membranes shall be ruptured and the uterus cleaned out, under an anæsthetic if necessary, the fœtus being extracted piecemeal. If the abortion had partly taken place it was better as a rule to give an anæsthetic and complete the operation.

Dr. A. LAWRENCE of Bristol said that when one was single-handed the best plan was to plug cervix and vagina with iodoform gauze; he thought that one should always explore with the finger before introducing the curette.

Dr. ALFRED SMITH of Dublin would divide cases into (1) those in which it was necessary to interfere; (2) those in which it was not necessary to interfere; in the first he would not give ergot, but gave cannabis indica. In the second he separated the ovum by the finger, and then expressed it by bimanual compression of the uterus. If the ovum was still in utero we should find the internal os contracted, external os dilated; if the ovum had left the uterus the opposite would be the case.

Dr. HAWKINS AMBLER of Liverpool said the most important preventive treatment was to treat endometritis by the curette. Where women were kept in bed for a long time the most obstinate constipation was apt to arise, which in itself was liable to induce abortion. He favored the curette in preference to the finger, and after curetting packed the uterus with iodoform gauze.

Dr. WILLIAM DUNCAN of Middlesex Hospital, London, said syphilis might produce abortion years after the father had been infected; he knew one case in which it was fifteen years after. He thought that heart disease was an important cause of miscarriage. In the treatment of threatened miscarriage, if there was no pain, he gave ergot in five to ten minim doses every hour. In the treatment of inevitable abortion he used an anæsthetic, placed the woman in the lithotomy position, and dilated, and cleared out with the finger, afterwards using 1 in 2000 perchloride solution with a curette.

Dr. INGLIS PARSONS of Chelsea Hospital for Women, London, said that we were frequently asked what exercise, etc., the patients might take with safety; he thought that, if they were fairly healthy, they might do almost anything; under such circumstances, bicycling, voyages, extraction of teeth under gas, were all safe. As an antiseptic he preferred chinosol and as a sedative viburnum prunifolium.

Mrs. STANLEY BOYD of New Hospital for Women, London, thought that plugging the vagina alone was sufficient; it was impossible to plug the cervix without fixing it with vulsella and thus causing a lesion which would be better avoided. As regards traveling, in cases where miscarriage had threatened, she had often been surprised by the safety with which women who had suffered from hemorrhage had borne a journey after the symptoms of threatened miscarriage had passed away.

Dr. HAULTAIN, of Edinburgh, insisted on the importance of obtaining a good dilatation before extraction; for fœtuses of five months the os should [illegible] the size of a crown piece (or a silver dollar).

THE PRESIDENT said that, in his opinion, [illegible] recurrent abortion was generally due to syphilis and [illegible] in doubt, mercury should be given to both parents. [illegible] flushing curette was better than the finger.

Dr. Horrocks, in reply, said that he regarded the finger as the best instrument. In his opinion, heart disease was generally associated with scanty menstruation and was not an important cause of miscarriage. It was better to remove the fœtus piecemeal than to waste time in trying to obtain further dilatation of the os when the hemorrhage was severe.

Deciduoma Malignum.—Dr. HORROCKS showed a specimen of this affection which occurred in a patient who was supposed to have had a miscarriage two years before. Under the microscope the specimen showed syncytium and decidual cells, and the growth invaded the vascular spaces; there were no blood vessels in the growth. The uterus was removed per vaginam, but the woman died in six weeks from secondary growth and hemorrhage.

Cæsarean Section.—Dr. MUNRO KERR of Glasgow read a paper on this subject, reporting three successful cases. In each case the operation was performed for contracted pelvis, the uterine wound was sutured, and the Fallopian tubes were ligated and divided. The speaker insisted on the great importance of a thorough cleansing of the vagina before operation. He discussed the question of sterilization and arrived at the conclusion that at the present time one would be perfectly justified in performing cæsarean section repeatedly on the same patient.

Dr. PURSLOW, of Birmingham, in a recent case of cæsarean section had turned the uterus out through the abdominal wound before opening it, and after extracting the child had performed hysterectomy.

Dr. HORROCKS said that the mortality of craniotomy at the present time was almost nil and it was unfair to compare modern statistics of cæsarean section with old ones of craniotomy.

Shock in Abdominal Operations.—Dr. HAWKINS AMBLER of Liverpool read a paper with this title. The time element, he said, was a main factor in the production of shock. In the preparatory treatment of patients for abdominal operation they were starved too much. He advised injecting one or two ounces of brandy high up into the rectum at the commencement of the operation. General anæsthesia was an element in its production, and he looked forward to a large future for local anæsthesia. In the treatment, flushing the abdominal cavity with a hot saline solution was an important element, and the patient should not be rigidly deprived of liquids after operation, but should be given water in sips and hot saline injections by rectum.

Dr. WILLIAM DUNCAN had found that shock most frequently occurred in cases of hysterectomy, and in these cases he was in the habit of giving three minims of liq. strychniæ hypodermically twice a day for a week before and a week after operation.

The Bacteria of Biliary Calculus Cultivated in the Bile.—F. E. Italia concludes from the results of experimentation that the bacterium coli commune and Eberth's bacillus are the specific organisms of cholesterin calculi. The streptococcus pyogenes and the staphylococcus aureus may rarely cause a biliary calculus, which will, however, be composed only of lime salts, these microorganisms not having the power to precipitate cholesterin. If the bacterium coli commune is associated with the streptococcus and the staphylococcus, its action in the bile will be increased in rapidity, and the resulting calculus will be a mixed one, composed of cholesterin, lime salts, and bile pigments.—*La Riforma Medica.*

BRITISH CONGRESS ON TUBERCULOSIS.

Held in London July 22-26, 1901

(Special Report to the MEDICAL RECORD.)

(Continued from page 230.)

GENERAL SESSIONS.

Fifth Day—Friday, July 26.

The final meeting of the Congress was held on July 26th, with the Earl of Derby in the chair. The following resolutions were unanimously adopted.

1 Tuberculous sputum is the main agent for the conveyance of the virus of tuberculosis from man to man. Indiscriminate spitting should therefore be suppressed.

2 All hospitals and dispensaries should present every out-patient with a leaflet on the prevention of consumption, and insist on the use of a pocket spittoon.

3 Notification of tuberculosis should be established, when possible. If compulsory notification is impracticable, voluntary should be encouraged.

4 The provision of sanatoria is an indispensable part of measures for the diminution of tuberculosis.

5 Medical officers of health should use all their powers and relax no effort to prevent the spread of tuberculosis by milk and meat.

6 In view of the doubts thrown on the identity of human and bovine tuberculosis, the government is requested to institute an inquiry into the subject.

7 The educational efforts of the great national societies for the prevention of tuberculosis are deserving of support.

8 A permanent international committee should be appointed to report on the measures for the prevention of tuberculosis in different countries.

9 Overcrowding and defective ventilation, damp and insanitary dwellings of the working classes diminish the chances of curing consumption, and are predisposing causes of the disease.

10 The attention of governments and charitable persons should be called to the necessity for establishing anti-tuberculous dispensaries.

The following subject was proposed for the consideration of the next Congress: The constitutional conditions of the individual which predispose to tuberculosis, and the means by which they may be combated.

These resolutions were in due form moved and seconded by different members of congress who made speeches in support of the proposals. There was in fact as one remarked, a good deal said, if but little beyond what had been previously asserted in the several sections.

SECTION II.—MEDICAL, INCLUDING CLIMATOLOGY AND SANATORIA.

Third Day—Thursday, July 25.

Sanatoria for Consumptives.—Professor CLIFFORD ALLBUTT opened the discussion on this subject. He had prepared a paper for the occasion, but owing to the shortness of time, instead of reading it *in extenso*, decided to give only the salient points and suggest certain queries for subsequent discussion—presenting the original paper to the Congress. A generation ago climate was considered paramount in the treatment of tuberculosis. But later it has been shown that excellent results, largely independent of climate, can be obtained by treatment in special institutions commonly called "sanatoria." The method itself, as he had shown in the full paper, was by no means new; but its testing, carrying out, and perfection were new. As to the question whether sanatorium treatment could not be equally well carried out in the patients' own homes, he had little confidence in such attempts. And it was in the congregations at sanatoria that not only the best routine, but the best individual treatment for each case was to be learned.

To speak of the best climate, best diet, etc., for consumption was vain, different cases requiring different management. To speak generally, the coldest air the individual could tolerate was the best for him, since it stimulated his appetite, powers of assimilation, etc. But a climate which a patient thirty-five years of age might bear with advantage would be quite inappropriate to an older person. Feeding should not be forced—overfeeding, especially at low altitudes, often started gastric troubles.

Every sanatorium worthy of the name should have a laboratory. Less time should be wasted in counting bacilli—which did not mean everything—and more given to the study of blood conditions, mixed infections, attenuation of virus, the varying virulence of bacilli, examinations of the secretions of the stomach, testing the urine for toxins, the effects of fever on metabolism, and such like problems.

The tendency of tubercle to become cured was considerable—if it were taken early enough. He would suggest that at least one-third of his hearers, at some time or other in their lives, had been infected with tubercle, and with little ill result. Every report which came to hand—the last he had seen being from the Hanse towns—emphasized the need of early treatment. If such were general he maintained that a great number of advanced cases would cease to occur. Whenever a patient was run down, or even off-color, one should suspect phthisis, cough or no cough. The absence of bacilli must not be taken as a sign of safety.

The duration of residence at a sanatorium must vary according as one expected an arrest of the process, obsolescence of the disease, or a *restitutio ad integrum*. As to the mean duration required for the first he would leave that to discussion. For obsolescence he suggested at least one summer and two winter seasons. For the last an indefinite period was required. The speaker had been latterly much impressed by the wise differentiation of cures by his German colleagues into two classes: economical or *wirtschaftliche* cures, and pathological or *wissenschaftliche*. How long a time must be devoted to an economical cure—that is, before a patient may return to his own home imbued with sanatorium methods? He suggested about six months.

If fever continued more than ten to fourteen days after admission we should be justified in giving a longer period for prognosis. If fever was prolonged four to six months, no good result could be looked for. Old patients and alcoholic ones did badly. In his opinion, a tuberculous pedigree did not count in the prognosis. Pregnancy was certainly very bad, while gout was a favorable factor. Cases of creptation at one apex must dry up in from four to six weeks if the patient is to come out in three months. As to bacilli, he would attach more importance to the progressive diminution of the sputum, rather than to the presence or absence of bacilli. In cases of phthisis complicated by tubercle elsewhere—*e. g.* lung and testicle—the outlook was bad.

The patient needed fresh cool air day and night, a good diet, but it must be borne in mind that man is at bottom a carnivorous animal and carbohydrates must be administered with care, especially to weak consumptives. He described cases he had seen of emaciated patients with their stomachs painfully distended. Milk, too, must be used with care at first. In addition to digestive difficulties it often, by adding to the bulk of the blood, overtaxed an already feeble heart. A good appetite came with fresh air, as cool as the patient could bear. Rest was necessary at first in all cases, febrile or not; rest in bed was needed, and very often rest for the stomach as well at first. Patients should rest also before and after meals, and if subject to vomiting should be fed in bed. Alcohol, even given medicinally, was always liable to abuse, and was rarely needed. Hydrotherapy was not now used as much as formerly, at Davos at all events. Pulmonary gymnastics were quite inappropriate to the softening forms or in cases of recent hemorrhage. High altitudes seemed to promote the same changes as respiratory gymnastics, but in a more gradual and less risky manner. He had little faith in the internal administration of drugs in phthisis; that is, courses of drugs. In laryngeal tubercle drugs often acted well, but it was then local application.

Lastly the vapid hours and aimless days might be avoided by suitable games for the more vigorous, and quiet occupation for others. The points he would submit to the meeting were: (1) Can mixed infection be inferred from the fever curves? (2) Can we discern between economical or *wertschaftliche*, and complete or *wissenschaftliche* healing? (3) How long in active cases is a febrile patient to be kept in bed with reasonable hope of recovery? (4) What estimate of improvement can be based on physical signs alone? (5) Is multiple tuberculosis too hopeless for a public sanatorium? (6) Is massage of any use? (7) Is hydrotherapy? (8) Are pulmonary gymnastics appropriate at any stage? (9) Need we repair the body at the expense of the intellectual life of the individual?

Dr. J. KINGSTON FOWLER outlined the development of modern sanatorium treatment. All were now agreed as to its value. The methods adopted could be carried out only in special institutions, at all events far easier and better there than at home. It was so much easier to do as every one else was doing. The aim was to render the lesions obsolete and send the patient out able to stand the stress and strain of ordinary life. This was often to be obtained without the complete disappearance of the bacilli. Besides the cure of the patients, sanatoria afforded an education for them and facilities for research on the part of the staff. As to feeding, the gain in weight depended largely on the amount of food ingested. But weight might be gained without the disease becoming arrested.

In making 1,943 post-mortem examinations he had seen nine per cent. of arrested tuberculosis. Sydney Martin had came to about the same conclusion. One hundred and thirty-four had become arrested at an early stage, while in forty-three excavation was present. One thus learnt from nature the curability of early tubercle.

Hospitals in towns are centers to which patients come. Much might be done in them to educate patients in the management of the sputum, etc. The practice of in-patient tickets should be given up and only out-patient tickets given to subscribers, selection of in-patients being left to the staff, as many valuable lives were lost through cases which might have been arrested having to wait months for a vacancy. He found that it took only two or three days for patients to become accustomed to fresh air, and had even found London fog (fires being kept going in the wards) no bar to treatment.

The speaker thought that among the working class, only the unmarried with no one dependent on them would be able to give the time requisite for the treatment. In the working class, also, relapse was very frequent after arrest of the disease in sanatoria; and opportunities for complete recovery, by engaging in self-supporting horticultural or other work in the country, before returning to the ordinary avocations of town life, were greatly needed.

Dr. R. W. PHILIP of Edinburgh spoke after ten years' experience with about 700 cases of sanatorium treatment. As to the systematic treatment there must be no hard and fast rule, each case being treated *per se*. Open air or hyper-aeration was the main agent, all were agreed. Exposure should be uninterrupted, and in his opinion there could not be too much of it. He used to have the temperature of the wards regulated by the thermometer. Now that had been quite given up. Free access of air day and night in all seasons was the rule, and the best results were obtained when the atmosphere indoors approximated to that outside. Their winter results under this régime were better than those of summer. He had had some patients sleeping out under an awning, and many of these literally ran ahead. The immediate indication on commencing treatment was rest—in some cases this must be long maintained. The pulse and temperature must be the guide. Patients often came in with a soft, quick pulse of 90 and a temperature of 100.5°. This altered with rest. Exercise would often temporarily send both up again.

Exercise was to be permitted as improvement proceeded and the need for rest lessened, the pulse and temperature being carefully watched; in some cases simple respiratory exercises were given. As to diet, it did no good whatever merely to cram material into the alimentary canal—the patient should be got to eat of his own accord, resting both before and after meals.

The skin being of such importance as a heat regulator, the hygiene thereof should be cared for. The rapid cold bath often did good. Clothing should be of Shetland wool materials. Chest protectors were wrong in theory and practice. The patient should be taught that consumption did not ensue from exposure but from bad ventilation. The only point of medication touched on by the speaker was to mention favorably the diagnostic therapeutic value of tuberculin.

As to sites for sanatoria—they should not be too far from town and not too far from patients' homes and friends. It was better to cure patients under their normal climatic conditions and to educate their friends at the same time. Both of the speaker's sanatoria were within three miles of the center of Edinburgh, and the results were uniformly good if the cases were taken early and the opportunity for lengthy treatment was given. The changes to be noticed in the patients were: Alteration of aspect to that of ruddy health. A gain of weight, sometimes as much as two to four pounds a week, or even eight. This gain meant good solid flesh, muscle as well as fat, and *pari passu* there was a disappearance of myotatic irritability. The temperature gradually modified—not necessarily because the lung condition was satisfactory, for the temperature might become normal with vomicæ present. The pulse from being soft and rapid became slow and resistant. Night sweats disappeared in a few days or weeks. Six months might be regarded as a suitable minimum for treatment and we might expect fifty to sixty per cent. recoveries.

Professor VON SCHRÖTTER of Vienna agreed that the main principles of sanatorium treatment were settled. But more scientific observations were needed as to the desirability of the sites for sanatoria, mountain or otherwise. What was needed was to have a central sanatorium say at 400 metres elevation, to have the patients there for, say, three months, so that they could be observed and conclusions drawn. Then a batch should be sent to the hills, another south, and so on, and the results should be collated. As to treatment, the proper place for the study of every new remedy was the sanatorium. Tuberculin he at first had opposed, but was now thankful to Koch for the many new views and lights that the introduction of tuberculin had thrown on phthisis. As to its therapeutic value it was not easy to decide. The good results of sanatorium treatment were about seventy per cent. Goetsch's results with tuberculin (acknowledged to be the best) were about the same. In view of the importance of having a full trial of the remedy he would once more ask Koch for a plain pronouncement as to how tuberculin was prepared.

Professor DVORAK of Prague spoke as to the need of isolation of tuberculous cases.

Dr. JANEWAY of New York, while admitting the value of sanatorium treatment, said it would be a very long time before we could hope to get sanatoria enough to accommodate the cases. Meanwhile what were we to do to prevent tuberculous individuals being a source of danger to the community? He would suggest sending them to cottages in the neighborhood of sanatoria, and having them treated by the sanatorium physicians. This system was to a certain extent being adopted by the well-to-do who had cottages in the neighborhood of a sanatorium at Saranac and were treated by the physicians of the institution. In this connection he would ask, where did the nine per cent. spoken of by Dr. Fowler get well? Sanatoria

he believed in, but it was necessary to get a sufficient supply for the poor first. The rich could be looked after in the way described above. It was highly necessary that the medical profession should detect cases earlier. Also it was well to remember that every lesion of the lungs in a tuberculous patient was not necessarily tuberculous. Many persons who described themselves as living "with one lung" were cases of slight phthisis in which a bad prognosis had been given because the physician examined them during an attack of intercurrent bronchitis or pneumonia. One should be chary of passing a sentence of death on a patient without waiting to see how much the signs would clear up under treatment.

Sir HERMANN WEBER, in answer to Prof. Allbutt's query as to how long fever may continue and yet the patient recover, said he had known a patient to have a temperature fluctuating between 98.5° and 103° for three years and ultimately recover. As to gout being favorable—in twenty-five of his cases of recovery eighteen had since developed distinct gout. He believed transitional sanatoria were much needed, where patients could be still under observation. And one must not overlook the individual peculiarities of the patient. He read a paper on a plea for sea-side sanatoria and pointed out how England, the pioneer in this matter, with its sea-bathing infirmary at Margate over a century old—now partly closed for want of funds—was outstripped first by Italy and latterly altogether by France.

Dr. S. A. KNOPF of New York pointed out that the early recognition of cases must depend on the family physician. As to sites for sanatoria, the climate where the poor lived and labored was the one to get cured in; and in the case of the rich also the institution should be as near home as possible, so as not to add nostalgia to their other troubles. He considered general opinion to be too pessimistic regarding pregnant tuberculous women. Sanatoria must also be worked in connection with district dispensaries where the convalescent and ambulatory cases could be cared for.

Dr. SNOW did not believe in forced feeding, but encouragement. Many of Prof. Allbutt's conundrums he would not attempt to answer. At Bournemouth sixty-three per cent. of their early cases left with the disease arrested. He would consider two years clear of symptoms indicative of a cure. Of the cases of softening forty per cent. were cured, and of more advanced cases eleven per cent. The results he considered were also more permanent under the new method. Consumption should be classed among the notifiable diseases. In practice it was found that the safest place against consumption was a sanatorium. He knew of no single case of an attendant contracting the disease. The well-to-do need sanatoria as well as the poor, in order to learn discipline. There was great virtue in change of air—after six months at a sanatorium a change often did great good. If a case showed no sign of improvement in two months, it was to be considered incurable and sent out. He firmly believed that consumption was a decreasing disease and bound to disappear.

Dr. ROSENTHAL of Copenhagen pointed out that in Germany, at a rough estimate 100,000 beds would be needed for the sanatorium treatment of all the tuberculous—a quite impossible number. It was therefore needful to attempt systematic treatment which might be carried out at a very small expense in existing institutions. He advised using bedrooms abutting on hospital gardens with a tent in the garden as a resting place in the daytime.

Sanatorium Treatment in England.—Dr. BURTON FANNING presented a report which had been drawn up at the request of the Congress on the experience of sanatorium treatment in England. He did not attach much importance to climate or weather. In England very good results were obtainable both in winter and summer, and in town hospitals too. A preliminary rest was a most important factor. Fever might persist a long time, but as long as a gradual slight lowering of temperature was noted one should be encouraged to persist. As to diet, one should feel the way, beginning with ordinary diet. In practice, weight was often increased when the diet was reduced. Massage and hydrotherapeutics had been little used in England. His own results from massage were poor.

Dr. WOLFF described a novel kind of sanatorium adopted to save expense. It consisted essentially of lightly constructed barrack buildings, near a town in a suitable locality, to which patients might go during the day and return to their own homes at night.

Dr. B. HARTNELL advised taking the temperature in the rectum, and said that when the temperature was fairly low rectal charting showed the oral readings to be inaccurate. In cases of high temperature, 103° and over, there was not the same discrepancy.

Dr. PARSONS of Dublin pointed out the very high mortality from phthisis in Ireland. He showed that the mean gain of weight from sanatorium treatment averaged only four ounces a week in March against about sixteen ounces in September to December. In his opinion sanatoria were necessary for the rich, but we could not expect much until medical men practised what they preached, and showed personally that they approved of fresh air in their own dwellings. His experience of sanatoria for the poor coincided with that of Dr. Walters of Nordrach, namely, that the patients very speedily relapsed. He therefore thought that the proper housing of the poor was at the root of the whole question.

Fourth Day—Friday, July 26.

Diagnostic Uses of Radiography.—The early portion of the morning was devoted to the consideration of the use of the Rontgen rays in the diagnosis of pulmonary consumption.

Dr. HUGH WALSHAM exhibited by lantern illustrations many radiographs of patients which showed the various deposits in the different lobes, infiltration of the bronchial glands, cavities at both apices and bases, and displacement of the viscera corresponding to the lung changes, as of the heart in fibroid phthisis.

Dr. BÉCLÈRE of Paris spoke about the technique of the method.

Dr. BONNET-LÉON of Paris directed attention to the information to be obtained by a practised observer in very early cases, before any obvious tuberculous infection was present, by being able actually to see how limited the action of the diaphragm was. That is, given a case in which the observer noted that the diaphragm was not contracting normally, and there was no sign of disease present to account for it, very early phthisis was probable.

Dr. ESPINA Y CAPO of Madrid also read a paper on the same subject.

Sanatorium Treatment.—Dr. SYMES THOMPSON of London read extracts from a paper, the chief points of which were that there was no special virtue in sanatorium treatment which did not obtain elsewhere, provided the leading principles were kept in view. Patients could be perfectly well treated in ordinary nursing homes, providing the medical attendant had sufficient strength of character to enforce the needful rules. In a sanatorium there was always danger that the individual might be overlooked, whereas in a nursing home his idiosyncrasies could be carefully watched. In touching upon diagnosis and observations on the progress of individual cases, the speaker said that variations of temperature in the mouth were unreliable, and that rectal temperatures should be the guide. As to Dr. Gordon's observations about phthisis and wind prevalence, he considered such fear groundless. Wind was the best ventilator, and continually changed the atmosphere around the patient. Possibly the fact that in windy districts people kept their windows shut,

more than in sheltered localities might be the true explanation of the prejudice against such places.

Dr. SQUIRE of London said that after preaching and practising the sanatorium or, as he preferred to call it, the hygieme cure of consumption for ten years, he was opposed to Dr Thompson's views about nursing homes. The essential point about hygienic treatment was the necessity for discipline, the inducing the patient to submit to rule. Thus, one could not but be struck by the difference in different sanatoria as to rules, except in the matter of fresh air. But the mere fact of having rules, of not permitting exceptions, of teaching the patient to obey, was the essence of the treatment. In nursing homes, when patients were not very ill the nurses were apt to drift into the intermediate position of nurse and friend, and thus the requisite authority was lost.

Another point was the difficulty of keeping up the temperature by fires when the windows had been taken out. As a matter of fact nurses and patients had in the North London Consumption Hospital given up fires as useless and troublesome. The patients were kept well warm in bed of course. Children of ten to twelve years did well in sanatoria, but patients about the time of puberty did very badly

Dr. F. MORINS of the Mont Blanc Sanatorium was of the opinion that the question of the site of a sanatorium was important. As a general rule he believed sanatoria should be in elevated positions. If individual patients showed indications for the selecting of any particular climate, they should of course be sent there, but in his experience such individual peculiarities on the part of the patient were rare.

Dividing his cases into the usual three classes, first, second, and third stages—96 per cent. of the first, 66 per cent. of the second, 51 per cent. of the third, had been benefited by treatment.

As to what cases were suitable for admission, it was well-known that the prognosis of tuberculosis was difficult and uncertain. He would hospitalize all the patients, and so give all a chance. They were in this way isolated, a source of danger to the community was removed, and an education was afforded to those who had to go out again, improved or not. As to the length of residence, he said, in the case of the rich, it should be until they were cured or as long as might be deemed wise; in the case of the working class (his institution was for them), he considered the oft-stated three months minimum as quite insufficient.

Dr. LOSALLE of Bordeaux regarded seaside sanatoria as preventive in the case of weak, debilitated and scrofulous children; and as prevention is better than cure, he advocated their extension rather than that of sanatoria for established tuberculosis. But the greatest need of all was popular education in this matter.

SECTION III.—PATHOLOGY, INCLUDING BACTERIOLOGY.

First Day—Tuesday, July 23.

The meetings of this Section were held in the Saloon in the Queen's Hall, situated immediately under and within easy access to the Museum. This afforded facilities for studying in the Museum exhibits forming the basis of communications made in the Section.

At the opening of the Section, the President, Dr. G SIMS WOODHEAD, made a few introductory remarks, but said that, in view of the important subjects for discussion, and the short time available, he would not detain his hearers by delivering a long address, and expressed the hope that the several speakers would confine themselves to the all-important scientific facts of the matters under discussion, and not go off into generalities.

The Tubercle Bacillus.—The first subject for discussion was: "The Morphological and Physiological Variations of the Bacillus Tuberculosis, and its Relations to (*a*) other Acid-proof Bacilli and (*b*) the Ray Fungus and other Streptothrices."

Dr ALFRED MOELLER of the Berlin Sanatorium, Berlin, said the discovery in recent years of "acid-fast" bacteria, other than that of tuberculosis, had rendered the diagnosis of the tubercle bacillus by the microscope alone impossible. There had been a considerable amount of discussion as to the cause of this "acid-fast" property Klein and Marmorek had recently shown that quite young tubercle bacilli do not exhibit it, probably from the absence of the waxy and fatty envelope present in the full-grown bacillus Borrel, by the prolonged action of warm xylol, had removed this waxy envelope, and the bacilli were then found to be no longer "acid-fast," though still capable of producing tuberculosis The bacilli, which closely resemble that of tuberculosis, and which have been known for some years, are the bacillus of leprosy, the smegma bacillus, and the bacillus of avian tuberculosis.

The characters of these, and the points in which they differ from the bacillus of tuberculosis were briefly described. Dr. Moeller then passed on to consider a series of organisms whose presence in our environment had been recently demonstrated, and which closely resembled the tubercle bacillus. Some of these, such as the Petri-Rabinowitsch and the Korn bacillus, occur in butter and in milk. The butter bacillus is not so resistant to acids as that of tubercle, and though, when it is injected into guinea pigs along with butter, appearances closely resembling those of tuberculosis are produced, yet an indurative peritonitis usually results as well. All the milk bacilli present such a close resemblance to the grass bacilli that Dr. Moeller considered we were justified in regarding them as modifications of the latter. The grass bacilli (timothy bacillus and grass bacillus ii.) resembled in staining reactions and morphology the tubercle bacillus, but grew more slowly and the temperature relations were different. Like all "acid-fast" bacilli, they produced on inoculation a pseudo-tuberculosis; they did not, however, appear to play any part in the etiology of genuine tuberculosis, and we still know the tubercle bacillus as a saprophyte only in artificial cultures. Babes has recently described actinomycotic formations after the subdural inoculation of tubercle bacilli in rabbits, and others have got similar results by other methods It would appear, however, that the tubercle-actinomyces differs from actinomyces bovis, in that the direct relation of a bacillus to a club formation can only rarely be shown. Lubarsch has shown that other "acid-fast" organisms can also produce actinomycotic formations. Although the tubercle bacillus is thus shown to be one of the highly organized myces, it has not as yet been kept constant in that form Perhaps, in course of time, the speaker said, the necessary conditions will be discovered, but in the meantime the tubercle bacillus is of most importance in the stage in which we know it best, *i.e.* as a parasite in the form of little rods.

Dr WILLIAM BULLOCH of London said that under certain conditions at present imperfectly understood, the tubercle bacillus may show filaments, true dichotomous branching, and club formation, and in the tissues, especially in experimental tuberculosis, it may assume a radiate arrangement—characters which from a taxonomic point of view bring it into close relation with a large group of microorganisms variously designated Streptothrices, Oospora, Nocardiaceæ, and more recently Actinomycetes (Lachner-Sandoval). With ordinary hydro-alcoholic solutions of basic anilin colors, the tubercle bacillus is stained with extreme difficulty and imperfectly If certain substances (anilin, para-toluidin, meta-toluidin, benzaldehyde, carbolic acid—in practice the latter is chiefly used) are added to the basic dyes, the penetrating power of the latter for the tubercle bacillus is increased in high degree, and on subsequent treatment with mineral acids (thirty-three per cent. nitric acid, twenty-five per cent. sulphuric acid) the color remains in the bacilli, so that they stand out prominently from other objects in whose association they may be This "fastness" towards acids,

discovered by Ehrlich, has had a great influence on the development of the study of tuberculosis, and at the present day the microscopical diagnosis is made with this method alone. This acid-fastness is, however, not specific to the tubercle bacillus, but is also possessed by a considerable number of other bacilli, and the microscopical diagnosis alone is not sufficient to differentiate the true tubercle parasite from other "acid-fast" organisms. There is every reason to believe that the bacillus of human and that of bovine tuberculosis are identical. The bacillus of avian tuberculosis presents points of difference, but these are not differences of species. There exists a group of "acid-fast," tubercle-like bacilli widely distributed in Nature, the identity or non-identity of which with Koch's bacillus is not proven. Contrary to former beliefs, the acid-fastness is not due to the presence of fat in the bacillus, as after complete removal of this substance the bacilli are still acid- and alcohol-fast. The acid-fastness is due to a body of the nature of a wax (Aronsom) which can be extracted by acid-alcohol-ether, boiling chloroform, and boiling benzene. This wax in itself is powerfully "acid-fast," but is unstainable by fat stains (Sudan III. and Ponceau R.). Besides wax and fat, which are present in relatively large amounts, the tubercle bacillus is composed of proteids (important among which is a variety of nucleic acid, described as tuberculinic acid—Ruppel) and salts (with phosphates predominating). After the removal of all proteids, wax, and fat, a substance remains which contains a considerable quantity of nitrogen, and from its reactions is probably chitin or some allied body.

After these papers had been read, the Section adjourned to the Museum and inspected the cultures and preparations exhibited in illustration of the remarks that had been made. Upon resuming the sitting, the following discussion took place:

Professor ADAMI of Montreal considered that it would be premature to lay down definite laws as to the identity or otherwise of the "acid-fast" bacteria. He laid stress upon the necessity of following the recommendation of the American Committee that all bacteriologists should work with standard media; by so doing, progress would be made in arriving at a solution of the problems they had under consideration. He referred to an exhibit of cultures in the Museum by Mr. Swithinbank, full details of which, and of the media used, were given in the descriptive catalogue.

Professor MCWEENEY of Dublin referred to the valuable work that had been done by Coppen Jones showing the relationship between the tubercle bacillus and the group of streptothrices.

Professor MARMOREK of the Pasteur Institute, Paris, considered that it was difficult to draw distinctions between the "acid-fast" bacteria by culture and by staining. The whole matter could be simplified only by means of animal experiment.

Professor ROSEL of Berlin also drew attention to the importance of arriving at a solution of the difficulty by means of animal experiment.

Dr. William Bulloch, in his reply, agreed that "acid-fast" bacteria injected into animals did not excite tuberculous lesions unless they were tubercle bacilli.

Tuberculous Milk.—A paper was then read by Dr. LYDIA RABINOWITSCH of the Institut fur Infektionskrankheiten, Berlin, on "The Infectiousness of the Milk of Tuberculous Cows, the Bacteriological Diagnosis, and the Practical Value of Tuberculin for the Extermination of Tuberculosis among Cattle."

The occurrence of tubercle bacilli in the milk of cattle suffering from general tuberculosis, or from tuberculosis of the udder, was established, she said, by numerous researches many years ago. It had been demonstrated experimentally that the milk of cattle suffering from incipient tuberculosis may also be infectious, even if the udder is not affected by the disease. In the year 1899, Dr. Kempner and the speaker had demonstrated that tubercle [illegible] in the milk of animals suffering from incipient tuberculosis when the disease could be detected solely by means of tuberculin. This fact was confirmed, the same year by Ostertag's observations conducted on mixed milk, and by the examination by Adami and Martin of milk samples of individual cows. The animals in all these cases presented no clinical symptoms of tuberculosis, but reacted to tuberculin. A further proof was furnished by the author's more recent observations on the milk supplied to infants in Berlin. No tubercle bacilli were found in the milk taken from cows which did not react to systematically repeated tuberculin tests. On the other hand, the milk from the animals which were not submitted to the tuberculin test contained tubercle bacilli, though these animals showed no clinical symptoms of tuberculosis. From bacteriological studies on the milk of animals with suspected tuberculosis of the udder, Dr. Rabinowitsch had arrived at the conclusion that the microscopical examination of specimens of centrifugalized milk sediment is not reliable, as certain bacteria in milk, which are, in the character of their growth, as well as in effect on the animal organs, similar to the bacilli found by Koch in butter, are very difficult to distinguish from the real tubercle bacilli. The only reliable test is the animal experiment, but this may be tedious and sometimes fallacious.

The frequency of tuberculosis among calves, as well as the great increase of tuberculosis among swine in recent years (the latter is, in 90 per cent. of the cases, to be ascribed to the tuberculous food), offer the best evidence of the assertion that the use of milk of tuberculous animals is the chief cause of the dissemination of tuberculosis among animals. The test with tuberculin, aided by clinical and bacteriological examination, furnishes the surest means of obtaining milk free from tubercle bacilli, as well as of rearing cattle free from tuberculosis.

Dr. MCWEENEY of Dublin believed that tubercle bacilli could not be demonstrated in the milk unless the udder was tuberculous, and thought that in a good many cases the tubercle bacillus gained access to the milk through want of cleanliness in dairy processes.

Professor NOCARD of Alfort showed some trocars used by him in the diagnosis of tuberculous mammitis. He pointed out the danger of spreading tuberculosis, more especially amongst pigs, by giving them the residues of butter and cheese making.

Professor WOODHEAD of Cambridge maintained, notwithstanding what had been said to the contrary, that if a cow suffered from mammitis and gave the tuberculous reaction, the milk from that cow was capable of spreading tuberculosis. He was also of the opinion that a good many cases of tuberculous disease of lymphatic glands of the neck in children were occasioned though the ingestion of tuberculous milk and tonsillar infection.

Dr. McWeeney was asked to reply and said that, after hearing the opinions expressed, he was inclined to modify his views.

Treatment of Epithelioma.—Hipolito Guiu y Gutiérrez describes the treatment of uterine and other epitheliomata by means of arsenic. He holds that the use of arsenious acid after the method of Cerny and Trunecek gives better results than any other remedy yet employed, that many superficial epitheliomata can be cured by this without operation, and that it is also a useful palliative in cases of inoperable cancer. In uterine cancer he says that he has obtained most gratifying results in all cases in which he has employed the arsenical solution. Wherever the cancerous growth may be seated, arsenious acid always manifests an elective action upon it, different from that of any other remedies which he has tried.—*Revista Ibero-Americana de Ciencias Médicas*

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, held May 27, 1901.

GEORGE B. FOWLER M. D., PRESIDENT

Some Observations on the Relations of the Alkalescence of the Blood to the Urinary Reaction.—Dr. HEINRICH STERN read this paper. He said that the night urine has a greater acidity than that excreted at any other time in the twenty-four hours. The retention of carbon dioxide is greater during the hours of sleep than during the waking hours. Researches conducted by him had demonstrated that although nutritive material affects the reaction of the urine somewhat, it does so incidentally, and that the diurnal variations in the reaction of the urine were inherent, and dependent upon vital processes. The reaction depends upon the reciprocal relation between the absorption of oxygen and carbon dioxide. His own experimental observations had demonstrated that there is no definite and fixed ratio between the alkalescence of the blood and the acidity of the urine. Observations on the relationship of the ingesta to the alkalescence of the blood showed that in the healthy organism the alkalescence of the blood is not affected by the quantity of food ingested. Other experiments undertaken by the author to determine the effect of taking by the mouth various alkalies, such as potassium bitartrate, showed that while the ingestion of these substances produced a pronounced alkalinization of the urine it produced no corresponding increase in the alkalescence of the blood.

Dr. LOUIS FAUGÈRES BISHOP said that the author had published an interesting paper on this subject about three years ago, and had been the first, he believed, to call attention to the fact that the daily fluctuations in reaction were independent of the ingestion of food. The experiments just presented certainly have a decided negative value. Personally, he was disposed to attribute the diminished acidity of the urine after the ingestion of food to the fact that, for stomach digestion, hydrochloric acid is required, and as this must be withdrawn from the blood there is less acid to be excreted by the kidneys.

Pregnancy Following Myomectomy.—DR. JAMES N. WEST presented this paper (see page 240.)

Dr. BACHE EMMET said that a most accurate diagnosis must be made in these cases before any intelligent treatment could be properly adopted. For this reason he regretted to see the tendency at the present time to neglect a very useful means of arriving at the diagnosis, *i. e.*, dilatation of the uterus and digital exploration of its cavity. The dangers of operating on these fibroids had not been emphasized in the paper, nevertheless they were still great, and until recently had been considered much greater in the operation of myomectomy than in that of hysterectomy. As a means of curing sterility myomectomy would often prove disappointing.

Dr. W. GILL WYLIE said that unfortunately the cases coming to the gynæcologist were often complicated ones, because these growths would go on for years without giving rise to symptoms. In a large consulting practice one would usually be struck with the comparatively small number of cases suitable for myomectomy, and in which permission to do this operation could be obtained. One must have an extensive experience with fibroids before being qualified to select the cases that are suitable for myomectomy. It was his belief that fibroids in young women may grow to a considerable size without doing any harm. In women over forty fibroids were apt to become degenerated, and if the woman of this age was to be exposed to the danger of an abdominal section, he thought it better to do the radical operation. Fibroids developing near the menopause were much more dangerous than in earlier life. Fibroids of the uterine wall, associated with endometritis, should be treated by hysterectomy. A woman after the age of forty with fibroids is more liable to have cancer than one who has no fibroids.

Dr. A. PALMER DUDLEY considered myomectomy a far more dangerous operation than hysterectomy, if done under perfect asepsis. He would not think of a myomectomy in a person approaching the menopause, nor would he wish to do this operation on a woman having a history of gonorrhœa or syphilis. He would prefer myomectomy to hysterectomy in a woman so situated that she could be well taken care of, but would select hysterectomy in preference to myomectomy for a working woman. He believed in myomectomy if properly done for selected cases. In many cases he would prefer to remove fibroids through a small incision by morcellement. If one object of the myomectomy were to cure sterility, the surgeon should not neglect, after having bisected the uterus, to inspect the tubes and make sure that they were patent. If the tubes were patent and the ovaries not diseased one had no right to sacrifice these organs in a young woman. It was different in a case of a woman approaching the menopause. He considered the paper under discussion as by no means enthusiastic; it was to be heartily commended, even though it did seem to bury certain treasured traditions. Because of the tendency to oozing of blood after myomectomy, it was his custom to drain the uterus—in his opinion, an exceedingly important point in the technique.

Dr. West, in closing, said that he was perfectly willing to plead guilty to the charge of being enthusiastic, and he thought there was good reason to be so over the possibility of checking the now too frequent mutilation and unsexing of women. It was the uniform opinion of pathologists all over the world that myamata do not undergo carcinomatous degeneration.

Some Further Remarks on Hospital and Dispensary Mismanagement.—Dr. THOMAS J. HILLIS presented only a portion of this paper for lack of time. He declared it to be an outrage to dump an assassin and a burglar in a hospital ward on either side of an honest and respected citizen who has gone to the hospital for treatment, and had paid his board in good faith. He was especially severe against the hospital managers who require those who pay their board to eat at the same table with those who pay nothing. The speaker was appalled at the amount of lying done at the dispensary desk, and averred that if the world-renowned expert in lying, Ananias, were in that crowd, he would, by comparison, dwindle into insignificance. Regarding the custom of compelling medical men to do their work in the hospitals without compensation, he said that while it is the province of the city to take care of its sick poor, as well as provide police protection and schools for the education of the children, the city officials never think of requiring the police and the school teachers to work for nothing. Even admitting the truth of the excuse offered, that the city does not give pay to hospital physicians because the latter are so eager to work for nothing, this simply showed a most unfortunate state of affairs, but afforded no justification for the city's taking advantage of the situation and demanding that skilled labor be given without pay. If it were argued that this were the result of the overcrowded state of the medical profession, what was to be said of the lawyers, who are five times more numerous in this city than physicians, and yet who always receive adequate compensation from the city for their services. The poor physician neglects his own business while working for the city for nothing, and in return the city shows its gratitude by seizing his home if perchance he has not been able to pay his taxes promptly.

Improved Home Bath for Typhoid Patients—Dr. RUSSELL BELLAMY exhibited an apparatus for the modern treatment of typhoid patients at home by bathing. He said that during his work at Bellevue Hospital he had been so impressed with the fatigue experienced by the

patient in the ordinary method of bathing, and the probable part played by such traumatism in the production of intestinal hemorrhage, that he had devised in 1894 an apparatus to remedy these defects. The present device was a perfected apparatus. The first bath should be at about 85° F., and this temperature should be gradually reduced in subsequent baths to 75° F. The bath should be given with frictions for about ten minutes. The bath tub exhibited was so constructed that by means of a windlass it would be easy to raise or lower the patient without the latter experiencing any jar or strain. A movable and adjustable rest for the head and shoulders was provided, and also a powerful pump for emptying the tub in houses where hose connections with a regular water service were not at hand.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 10, 1901.

	Cases	Deaths
Measles	99	13
Diphtheria	133	22
Laryngeal diphtheria (croup)		
Scarlet fever	108	11
Smallpox	36	13
Chickenpox	4	1
Tuberculosis	230	144
Typhoid fever	67	15
Cerebro-spinal meningitis		3

Distinction Between Tubercle Bacilli and Other Objects.—W. D. Severn (*Medical Times and Hospital Gazette*) says that there are certain bodies which retain carbol fuchsin more or less obstinately in the presence of mineral acids, and some of these are occasionally liable to be mistaken for tubercle bacilli. Among these are minute fibres, needle-shaped crystals, smegma bacilli, the shrunken edges of some epithelial cells, and certain other bacilli when these have been in contact with fatty matter or chylous urine. These risks are much diminished by thorough staining and complete decolorization. By these means and a thorough knowledge of the morphology of the tubercle bacillus, the error due to the smegma bacillus is entirely eliminated. The color of the latter organism after staining, its shape, and grouping, are entirely different from those of the tubercle bacillus. And in the case of the other objects specified, it is practically impossible that more than one would be noted so exactly simulating the tubercle bacillus as to cause a wrong conclusion to be drawn, and surely no one would decide on the evidence of a single bacillus. The bacilli derived from a lesion in the urinary tract are a little smaller and somewhat more pointed at the ends than the larger sputum forms. Their protoplasm is generally homogeneous and stains brilliantly. When grouped, they may be simply matted together, or arranged more or less parallel to the long axis of a pre-existing "S-shaped" colony. One or two isolated, badly stained, highly "beaded" bacilli in a preparation may mean an accidental access of bacilli to the urinary tract in a case of miliary tuberculosis, and not an actual lesion in the kidney, bladder, prostate, etc.

Ulcer of the Stomach.—A. B. Mitchell (*Medical Press and Circular*) concludes (1) Surgeons have not yet devoted sufficient attention to ulcer of the stomach. Ulcer is more commonly anterior than is generally acknowledged. (2) Those ulcers which do not resolve under medical treatment give rise to grave complications in direct proportion to their duration; these complications include pyloric obstruction, hourglass contraction, involvement of neighboring organs, and attacks of peritonitis resulting in troublesome adhesions. (3) There is no more serious surgical complication than extensive adhesions, owing to their tendency to involve large vessels, nerve-plexuses, and vital organs. (4) When there are extensive adhesions it is probably better to leave them alone and provide for rapid emptying of the stomach by gastro-enterostomy. (5) When the ulcer is on the anterior wall it may be possible to infold or excise it, which is the ideal method of treatment; but when posterior, this will generally be omitted in favor of gastro-enterostomy. (6) Posterior gastro-enterostomy is the operation of choice; it is quite as easy to perform as the anterior operation, sacrifices less of the jejunum, and establishes the new opening at the most favorable point for stomach drainage. (7) The simple and continuous suture is to be preferred for this and similar operations, without any artificial support. The abdomen should never be opened without a Murphy's button at hand, though the necessity for its use will not be frequent. (8) In patients past middle life early explorations must be more frequently undertaken if the gastric surgery of this period is to attain the triumphs to which it is entitled.

Differential Diagnosis of Appendicitis.—A. J. Ochsner (*Medical Standard*) says that acute appendicitis is most commonly mistaken for the following conditions in the order named: (1) Gastritis or gastric ulcer; (2) enteritis; (3) gall-stone colic; (4) peritonitis, due to infection through the Fallopian tubes in women; (5) extra-uterine pregnancy; (6) renal colic; (7) perforative intestinal ulcer, due to typhoid fever, tuberculosis, actinomycosis, or carcinoma; (9) intussusception; (10) strangulated hernia; (11) intestinal obstruction due to bands of adhesion.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 10, 1901:

THE PROGNOSIS OF TRAUMATIC HYSTERIA, BASED UPON THE SUBSEQUENT HISTORIES OF A NUMBER OF LITIGATED CASES.*

BY PEARCE BAILEY, M.D.,

NEW YORK.

IT is safe to say that some day or other every physician and surgeon will be confronted with a case of traumatic hysteria. The disease may be easy of recognition, but it may also present diagnostic difficulties for the most expert. In only a few places are adequate descriptions of it available, and even the most comprehensive treatises are incomplete in the details which are important for prognosis. The reason that our knowledge is particularly defective concerning the patient's prospects for a return to health is closely bound up with legal questions. By far the larger number of the cases of traumatic hysteria are made the bases of personal injury claims, and many of them are litigated. When the case is settled, or the trial is over, the plaintiff, who is the patient, disappears from view and what becomes of him is very hard to find out. It is astonishing how few of such cases are on record in which the patient's subsequent career is mentioned. During the past few years, a number of opportunities of obtaining such information have come to me, thus enabling me to arrive at certain conclusions which possess more than a theoretical value. Upon these cases and upon other non-litigated cases of personal experience the present paper is chiefly founded.

It is easy to understand why hysteria is often misunderstood and the sufferer from it misjudged. The disease, though essentially mental, finds its most conspicuous expression in physical symptoms. These physical symptoms are perplexingly similar to those caused by diseases of known material basis, and consequently the patient is, in general appearance, not a person suffering from a mental disorder, but one afflicted with some severe bodily infirmity. The most important material manifestations which hysteria causes are paralysis, and defects in the special sense apparatus of sight, taste, smell, hearing, and common sensibility, so that the patient may seem, and believe himself to be, paralyzed, or blind, or deaf, or deprived of the use of the other special senses.

These symptoms differ in mode of origin, in association with each other and with others, and in character, from those due to recognizable injury of the nervous system, and the trouble would be sought for in vain, either in the sense organs themselves, or in the direct central connections of the sense organs, or in the specialized brain regions which have to do with the registration of sensorial impressions. These comparatively simple structures remain normal in their function. The defects must be allocated to far higher spheres; to the neurone systems which have to do with the collection and elaboration of the products of sensorial impressions; to the domain of higher consciousness and personality; to regions concerning which psychology may speculate, but about which pathological anatomy is dumb.

In hysteria, the normally transmitted and normally registered sensory stimuli in some subtle way fail to be transferred to association systems. Hence they do not enter into the practical life of the individual, and do not attain an intellectual value. The patient consequently is in the anomalous condition of feeling, seeing, hearing, tasting, or smelling, as the case may be, without being aware that he does so; or, from similar or more complex causes, he may lose the power of originating voluntary motor impulses, and be, for all practical purposes, paralyzed. Yet the belief of the patient as to his own incapacity is absolute and often so persistent as to deprive him of his usefulness for considerable periods of time. Since the belief is false, and since false beliefs which dominate and disorganize the life of an individual are insane delusions, hysteria deserves to be classed with the delusional insanities.

Without lingering further on generalities, a number of cases from personal experience will now be narrated, which have been observed during the past few years, either in the office or in the court-room. Were the full details of the examination of each of these cases to be given, this paper would be much more tedious than I intend it shall be. I must ask that my assurance be accepted that each case was studied with great care, and that in each case the diagnosis of traumatic hysteria was made only after considerable reflection and with full appreciation of the opportunities of error. No case is presented here in which there is the slightest doubt in my mind as to the correctness of the diagnosis.

CASE I.—Up to November 10, 1896, A. B. was, according to his own story and that of his wife, a healthy, happy, and prosperous farmer, fifty-six years of age. On the evening of that day he was in an accident, in which he was neither cut nor bruised, and though somewhat dazed he was able to walk home, a distance of several miles. He did not sleep well that night, and had some pain in his head and back. On the following day began a train of symptoms which still existed at the time I examined him, about a year after the accident. The symptoms consisted in the first place of a variety of emotional disturbances. He was depressed, he was tearful, and the most trifling contradiction broke him down, as he said. He was very apathetic and inattentive, and during my examination did not seem to be in the slightest degree interested. He gave up his farm work almost altogether, his wife said, and would sit for hours doing nothing, and interested in nothing. Physically he looked perfectly well, but he had a total loss of sensibility on the left side of the body, he dragged his left leg and staggered in walking. His wife said she would see him in the field when no one was watching him, and he then would stagger, always to the right. The dynamometer registered right hand 105, left hand 65. Thus the man presented the emotional state characteristic of traumatic hysteria, with a left hemiplegia and left hemianæsthesia.

Although it is now four and a half years since the accident, this man's claim against the person he alleges

*Read at the twenty-seventh annual meeting of the American Neurological Association, at Boston, June 25, 1901.

to be responsible for the injury is still unsettled. For that reason, fuller details of the case are not given here. The symptoms to-day are about the same as they were three years ago.

CASE II.—Mrs. R., who was an actress, thirty-nine years of age, was in a railway collision on Sunday, the 31st of May, 1897. She was sitting asleep on a seat with her feet up on the seat in front of her, when the car she was in was struck by a car from behind. She does not remember anything until she found herself standing up between the two seats. She was very much frightened and jarred, though she sustained no cuts or bruises. She continued on the journey, arriving at her destination at 4 o'clock Sunday afternoon. She stayed in bed until Monday night, and then went to the theatre and played, and was still playing every night when she was examined by me on the 28th of February, 1898. For the first six weeks after the accident the following symptoms were prominent: Pain in the back, sleeplessness, easily excited and irritated, difficulty in fixing the attention, poor memory, although her failure of memory was noticed only by herself; and difficulty in walking. After six weeks her symptoms improved, but she still had difficulty in walking, with a tendency to stagger to the right. My examination showed her condition to be similar to that of A. B., though much less serious. There was a slight left hemiplegia, and left hemianæsthesia with disordered mental state. She was liberally compensated by the railway company against which she entered a claim. I have heard from the railway company that they had good reason to suppose that before the accident she was an extremely nervous woman, and more or less of an invalid. This contradicts Mrs. R.'s own statement. Whatever may be the truth in regard to this she certainly has been in no way incapacitated from working. The last news I have heard from her she was billed to play in Kansas City in a stock company, for the season of 1900 and 1901.

CASE III.—The case of S. *vs.* B. occupied three days of the time of a Supreme Court justice, of twelve jurymen, many witnesses, numerous lawyers, and a large company of doctors. The suit was for $25,000, and what I know about it was gained from my presence in the court-room, as the plaintiff's attorneys would not allow me to examine her. The plaintiff was a young girl, unmarried, twenty-two years of age, and without occupation. There was conflicting testimony as to her health before the accident, but there seemed some reason to suppose that she had had hysterical attacks, and St. Vitus's dance. The accident from which this young lady reaped a rich reward took place on October 25, 1897. An elevator in a store got caught between two floors, and the passengers were imprisoned there for about fifteen minutes. Then the elevator fell thirty feet on to the rubber cushions below. The speed of the fall was estimated at three hundred and fifty feet a minute. Of the fifteen people in the elevator, none had bones broken, and none was badly bruised. All walked out of the elevator. The plaintiff was taken home in a carriage, and walked up two flights of stairs. She then had a nervous outbreak of great violence. She went to bed screaming and howling, and was so violent that she had to be held. For two days she lay without having her clothes taken off, and for seven days she lay with her eyes shut. She then developed the characteristic picture of left hemiplegia and left hemianæsthesia. The testimony of the plaintiff's experts reflected little credit upon their professional ability. They all said that she had sustained an injury to the spinal cord and that she was hopelessly and irremediably crippled for life. The plaintiff was in the court throughout, walking in on crutches. She had a violent hysterical attack in the witness-chair, so that her testimony had to be temporarily discontinued. The jury found in her favor a verdict of $11,500. About six months after the trial she was married. I have been unable to get any definite information since then. A person who saw her a year ago said she still walked with a cane.

CASE IV.—F. H., when I examined him on June 1, 1899, presented all the appearances of a badly crippled man. The left arm, forearm, and hand were held motionless, the muscles of this extremity being contracted in flexion. Any attempt to overcome this contraction caused the patient to give expressions of great pain. The left leg the patient said he could not move at all, but that power was really retained in it was shown by the fact that when I lifted it up, the patient held it out horizontally. It took a great deal of persuasion to get him to try to walk, and he dragged the left leg after him. He said he would fall if not supported, yet when I, standing behind him, withdrew all support, he did not fall. The left hemiplegia was complicated by a left hemianæsthesia. The visual fields were markedly contracted. These symptoms had existed for about one year before my examination. They first appeared after an accident on the railway in which the patient had been badly shaken up and frightened, but not injured surgically. Since the accident, the man had been entirely incapacitated from work. Shortly after my examination, the case was settled for $4,000. Six months later, the man returned to work, and has been working ever since. His family physician, Dr. E. D. Woodhull, of Monroe, N. Y., writes me under date of May 1, 1901, "He still has considerable pain in the left side of his head and in the calf of left leg. Is able to do a fair day's work, and work does not make the pains complained of worse. He is gradually improving, and will, no doubt, make a complete recovery in time. His back also gives him some trouble, but is much less painful than the head and limb. Eye-sight regained completely."

When electric power for purposes of lighting and transportation was first introduced into cities, there was a considerable increase in traumatic hysteria. Since wires now, in New York at least, run chiefly underground, electricity as a cause of the disorder is less prominent with us. When it acted as a cause, it almost always happened that it was not the electricity itself that did the injury, but the fright which persons underwent in touching electric wires. More frequently than not, in such cases, there were no burns whatsoever, and in some cases it was shown that the wire was dead at the time it was supposed to have inflicted the injury.

CASE V.—H. B., aged twenty-two, was a gay and imaginative young man from one of our southern states. He was a Hebrew, and consequently somewhat predisposed to the development of nervous disorders by reason of his race. In November, 1899, he touched an electric trolley wire with the left hand. He said he received a severe shock, but he was not rendered unconscious. His hand was not burned at all, nor was it incapacitated immediately. He was made very nervous by the shock, and went home and went to bed. He required no help in going to bed. The next morning he awoke and found he could not use his left arm. That member was still paralyzed when he came up from the South to see me the following December.

My examination showed a flaccid paralysis of the whole left upper extremity. He could do nothing with this arm whatsoever. With the exception of that arm he felt very well, and had no emotional disturbances. This young man was settled with for a small sum a few months after the injury. He rapidly

recovered and has been perfectly well ever since.

Case VI.—Another case very similar to the preceding was that of a Hebrew, a dry-goods clerk, twenty-three years of age, who in August, 1898, touched an electric wire with an umbrella which he was holding in his left hand. He fell down, suffering great pain in the arm, and was taken to the hospital. There was no burn. The examination showed the left arm to be held flexed at the elbow and wrist joint, and any attempt to move it caused expressions of great pain. The hand was mottled and cold.

This man brought a suit against the company. Before the case came to trial, he was etherized by his family physician, who then told him he thought he was a fraud. From that time on the arm improved greatly. A short time afterward he was awarded a verdict of $500, and since then he has been able to work, and is apparently well.

Case VII.—The following case was tried in Virginia during the first four days of May, 1900. During that time I was present in the court-room in behalf of the defendant, but I was not permitted to examine the plaintiff. One of the physicians associated with me in the case had, however, examined the plaintiff, and the following statements are the results of his examination and the testimony which appeared in the course of the trial.

W. P., a previously healthy farmer, with the exception of shortening of the right leg, due to an old fracture of the thigh, and of good habits, on the 8th of September, 1899, was in a cart which was run into by a trolley car. P. remembers nothing about the accident. It is doubtful whether he jumped out, or was thrown out of his cart; however that may be, he picked himself up and walked to the sidewalk, where he apparently became unconscious. He was carried to a neighboring house, where he had a violent convulsion. He struggled with a number of men who were standing around him, arched himself so that only head and heels touched the floor, and altogether gave a theatrical display. He then apparently became unconscious, and was carried to the hospital, where he remained in a stupid condition for twelve hours.

Examination at this time by the company's surgeon failed to show any contusion, wound, or other evidences of organic injury. The following day the patient complained of great pain down the right side. There were also twitchings of the muscles of the face and of the left arm. In a day or two the pain switched to the left side, being complained of over the scalp and in the arm. He began to improve until the 21st of September, when a fire broke out in the hospital. There was great confusion and fright at the time, and the nurse came to P. telling him to get up and get out, or he would be burned up. P. told the nurse to save herself, as he would rather be burned up than get up. She half pushed and half pulled him up, and then he was carried out of the hospital. He declared that he was not frightened by this conflagration. He was taken to his brother's house, and for a week or two afterward showed no ill effects from the fire. Early in October, however, he became deaf and dumb. He said that ever since the accident it had hurt him to speak, and there seems to have been some difficulty in speaking before he altogether stopped talking. A week or two after becoming deaf and dumb, the pain changed from the left side to the right, the patient stopped using the right hand almost altogether, and also the right leg, and from that time on he has held communication with others altogether by writing. He never lost the power of reading, and learned to write with the left hand very quickly. The above-described condition remained about the same at the time of the trial. P. was brought to the court sitting in a chair. He looked well, had no paralysis about the face, but had an almost constant twitching of the muscles of the lips, neck, and left arm. The right arm was not moved at all; the right hand was supported in the left much of the time, the fingers of the right hand being held straight and slightly flexed on the metacarpus. When he first came into the court-room, he had an attendant put his right leg over the left, and he held it in that position without moving it for the two hours and a half he was on the stand. The questions which were asked him in direct and cross examination were written on pieces of paper, and P. would write his replies beneath them. He grasped the meaning of the questions at once, and wrote as quickly as can be expected of a man who has only written with the left hand a short time. His answers were intelligent and pertinent. He gave no special evidences of fatigue, and was not emotional. On one or two occasions it seemed as though he had heard what was being said, although I can't be positive about this. Altogether he conducted himself very well. All the medical testimony was to the effect that P. was suffering from traumatic hysteria. My testimony differed from that of the other experts of the other side in the following points: They held that the fire had no effects on this man. This point had been brought up by the defence, in order to show that the fire and not the accident caused the deaf mutism. I held that such a supposition would be entirely contrary to the accepted theories regarding hysteria. They held that complete recovery from hysteria which had lasted so long, and which had presented such grave symptoms, was impossible. I held that recovery from hysteria was never impossible, and that when litigation was ended the plaintiff would probably recover in time, provided he could have proper treatment. I held that physical injury was relatively unimportant in the causation of hysteria, as the disease was essentially one of fright. I maintained that P. could perfectly well have had the same symptoms without having undergone any physical injury whatsoever.

This suit was the second one in this case. It was for $20,000. In a previous suit, in March, 1900, the jury disagreed, probably on the ground that recovery of damages is not possible for personal injuries, unless some physical injury can be proved.

In this suit, also, the jury failed to reach a decision. To avoid the expense attendant upon a third trial, the case was finally settled. Proper treatment was not instituted. In May, 1901, one year after the trial, this man had improved but very little. He is still deaf and dumb; he has severe headaches, and he falls down and hurts himself. The twitching in the face continues. He can get around on his feet, but drags the right leg in walking.

In the following case the mental state was the most important element, and without careful physical examination, the diagnosis of traumatic hysteria would have been difficult.

Case VIII.—J. K. was brought to me last September, on account of injuries alleged to have been received in an accident on March 20, 1900. He was a Bohemian, twenty-four years of age, a baker, with a negative family history, and always well up to the time of the accident. On March 20, 1900, he was run into by a trolley car while driving a cart, and was thrown out on the street on his head. He was unconscious for a few minutes. He sustained a scalp wound, but no fracture. He was somewhat dazed, but not very much excited. He could talk and walk, but from that time until the time I saw him he complained of great pain in the back of the head, and in the neck; he was sleepless; he was dizzy, and he was extremely apathetic. Altogether he presented the picture of a man laboring under extreme mental inhibition, and I doubt not that he

was seriously incapacitated for his work. Although the mental state was characteristic of severe grades of traumatic hysteria, it would have been impossible to be certain as to the diagnosis had it not been for the presence of a loss of sensibility on the whole left side of the body, and a contraction of the left visual field.

This man received a verdict of $1,400 in January, 1901. Soon afterward he left the town in which he had lived. In May, 1901, he was seen and questioned by one of my nurses. He was looking well, and working at full wages. He still complained of some dizziness and pain in the back.

The question of simulation naturally arises in all these cases. It is one which is sometimes difficult to decide. If the patient has well-marked and typical stigmata of hysteria, such as characteristic anæsthetic areas, and characteristic palsies, and especially limitations of the visual field, there is little chance of simulation, and there is little doubt that the patient believes in the reality of his symptoms. In the absence of all these signs, however, and when the patient's symptoms are entirely subjective, it is oftentimes impossible to decide as to simulation. In most of such cases the patient has some slight disturbances which he exaggerates.

Case IX.—J. N., while excavating a trench on the 8th of November, 1898, was struck in the back by a wheel of a wagon. He was taken to the hospital, and discharged in a few days. A year and a half afterward his case was tried in the Supreme Court in New York. A few days before the trial, I examined him in the presence of his attorney and of his physician.

The patient walked into the room leaning on a cane, and apparently suffering great agony at every step. There were no indications of motor paralysis in the gait. The examination showed all eye movements normal, pupils equal, responding promptly to light. No palsy of cranial nerves. Patient sat with his eyes half shut, saying that he had lost the power of opening his eyes, yet when I snapped my fingers loudly over his head, and told him sharply to look up he opened his eyes perfectly. There seemed to be some blunting of sensation all over body. His statements as to sensibility were very contradictory. He would say one minute that he felt the testing object, and at another that he did not. The muscles of the leg were well developed, responded perfectly to electricity, and the knee-jerks were normal. There was never any bladder trouble; the urine contained no albumin. The man complained of great pain in the sacral region. As he sat in the chair, he said it was impossible for him to straighten his legs out, on account of the pain in his back, yet he was perfectly able to get up from the chair, and walk on his legs. Before the examination was fairly begun, I ran my hand down his back. He did not notice the object of this, and did not complain of pain, yet when any movement toward moving his back was made with his knowledge he made exaggerated complaints. There was no prominence on the back, no depressions. He said he could not lie on the sofa for further examination, as it was too painful, yet he said he went to bed every night.

The plaintiff's case in this action was materially aided by the testimony of several physicians whose conceptions of nervous diseases were decidedly hazy, and who testified that this man's nervous system had been terribly lacerated and shattered. The jury awarded a verdict of $9,500. Before the case was finished the defendant's counsel, at my suggestion, said that in view of the absolute contradiction in the medical testimony, he would like to submit the plaintiff to an examination by any qualified experts that the court would decide upon, or else let the physicians of the two sides examine the patient in open court to determine which were correct as to the existence of symptoms which one side denied and the other confirmed. All these propositions were denied.

From the cases which have now been cited, it is evident that the same uncertainty regarding prognosis which characterizes all mental affections is to be found in traumatic hysteria. The patient may recover, having suffered but little, or he may carry the burden of his infirmity for years.

It seems to me that this latter point requires special emphasis even to-day. For in spite of the advances of our knowledge of psychological medicine since the time when traumatic hysteria was first written about, physicians generally believe that there is nothing the matter with hysterics, that they are posers and gallery-players, and that once they are paid for their fancied injuries, they will be as well as they ever were. In such opinions, the fact seems to be lost sight of that a fixed idea may disorganize the life of an individual as much as a surgical injury, and that it may at any time take root so deep that it can never be gotten rid of. Such possibilities are present in every case of traumatic hysteria. There are certain indications which enable us to predict them, or which make it doubtful that they will occur.

The first of these in natural order is heredity. In traumatic hysteria, as in all nervous and mental diseases, bad heredity throws an ominous shadow on prognosis. Instability of nervous function is the natural birthright of the children of the insane, the epileptic, the alcoholic, or the degenerate from any cause. We assume that such tainted individuals are particularly prone to develope mental anomalies from slight causes. And we know that once the neuropathic seed is sown on such soil the resulting growth is rapid and hard to check, and apt to be permanent.

But the teaching of Charcot, that hysteria never develops except in persons who are hereditarily or acquiredly degenerate, is very difficult to substantiate. My experience with traumatic hysteria has been that in a very large proportion of cases no predisposition to nervous or mental disease is to be discovered. It is true that litigation tactics often render inquiry as to such factors unsatisfactory, if not misleading. But when due allowance is made for unavoidable imperfections in investigation the fact remains that the larger majority of the vicitims of traumatic hysteria have as good family records as most people, and were quiet, orderly, healthy citizens up to the occurrence of the accident.

From cases presenting a fairly clean record should be carefully differentiated the ones in which undoubted hysteria existed before the accident, and in which the mental shock or the physical commotion did nothing more than intensify or vary pre-existing symptoms.

Bremer (*Your. Nervous and Mental Dis.*, 1893, p. 13) has recorded a case illustrating this. The patient brought suit for $20,000 for astasia abasia which developed in direct sequence to an accident in an elevator. Bremer was able to show that the plaintiff had had previous hysterical accidents and that the astasia abasia was not a new disease, but only a new symptom of a disease from which she had been suffering for years. By virtue of his testimony a verdict favorable to the defence was rendered. I take it that in the case of S. *vs.* B., already cited in this article, a similar condition of affairs existed.

Age is one of the most important considerations in the prognosis of hysteria, whether traumatic or non-traumatic. The older the patient, the greater is the danger that the symptoms will be permanent. In young children the physical symptoms of hysteria almost invariably pass away in the course of a few weeks. In a little girl of five years, whom I saw a year ago in consultation, there developed in consequence of a fall on the face, a complete right-sided

hemiplegia. Recovery was perfect within four weeks, and the child has been well ever since. Contrasted to the almost universally favorable prognosis in extreme youth is the regularly grave one in old age. Hysteria is infrequent in old people, but that it occurs is well attested. In them it is always a rebellious and persistent affection, oftentimes showing no amelioration whatever.

Between the two extremes of childhood and old age, the prognosis is better or worse as it inclines to the one end or the other of the scale. With patients under thirty-five years of age, if they are not seriously handicapped by heredity, and if the treatment is begun within a reasonable length of time, recovery can be confidently looked for in the vast majority of cases. But after the thirty-five-year limit has been reached or passed, the mind seems less able to throw off the impressions made by severe shocks and frights. In the middle-aged and elderly, consequently, traumatic hysteria is always a serious matter, and while restoration to health, if the conditions are favorable, is to be expected, it is not by any means the rule.

The previous condition of health of the victim of the accident has important bearings upon the severity and duration of the hysteria. In the healthy and well-nourished, there is naturally more hope that the psychosis will be temporary.

Pre-existing chronic diseases, on the other hand, make it more difficult to throw off hysteria.

Alcoholism and arterio-sclerosis seem particularly unfavorable to the recovery from functional nervous diseases. In this latter condition is doubtless to be found the persistence of hysteria in the aged. The question of sex is generally supposed to be an important one in traumatic hysteria. Most authorities agree that men recover less frequently than women. In my experience with litigated cases, men are much more frequently attacked. But there is hardly sufficient data to decide that in them recovery is less probable. It seems to me that the question of sex is very subsidiary to other factors.

The fundamental cause of hysteria is to be found in the mental state, and it is consequently to the mental state we must look for the most reliable guiding lines to prognosis. The physical manifestations offer a certain degree of help in determining how far-reaching the effect of the accident has been upon the mind. Thus a monoplegia indicates less serious psychic disturbance than hemiplegia, and monoplegias usually recover rapidly. Paraplegia, as a result of traumatism, is distinctly rare. I cannot recall having seen more than one or two cases. But if it resembles in its course the non-traumatic hysterical paraplegia, it will be found a most rebellious affection. Morbid movements, such as twitchings, choreiform spasms, hiccough, cough, and the like, are usually insignificant, and yield readily to suggestion. Anæsthesia and limitation of the visual fields are such important symptoms that without them the diagnosis of traumatic hysteria is open to doubt. They give a clue to the mental state by their intensity, and by the extent of their distribution. Shifting, inconstant, and partial anæsthesia is of much more favorable omen than the anæsthesia which is profound, and which settles itself in one place and stays there.

Of the affections of the other special senses our information is too meager to justify any broad generalizations as to prognosis. In my experience disturbances of taste, except when complicating hemianæsthesia, have occurred exclusively in the mildest cases. Hysterical blindness and deafness may be very serious affections. Aphonia is usually of a few days' duration only. From one of the cases described in this paper, it will be observed that hysterical deafmutism may persist without improvement for a year after all legal questions are at an end.

The physical symptoms just enumerated are without doubt useful indices as to the severity of hysteria. But they are indices only, and may very well have taken their particular form from some trivial causative factor or some chance environmental circumstance. They may change completely in character or in distribution, and still leave the patient as badly off as before. It seems to me that it is a great mistake to be guided too much by the physical symptoms in attempting to reach a prognosis in this peculiar malady.

The mental state is the fundamental cause, and the patient's purely psychological characteristics of attention, of memory, of mood, emotion, and temperament, of will, and of conduct, are the most important prognostic considerations.

In every case of traumatic hysteria these mental attributes undergo change. And in the extent of the change, and its permanence, is the key to prognosis. In other words, the prognosis of hysteria demands a psychological study of the individual rather than a simple enumeration of the physical manifestations he may present.

In conclusion, it may be said that the chances for recovery from traumatic hysteria in a previously healthy person not over thirty-five or forty years of age are generally very good, but are not absolutely certain. With increasing age the prognosis becomes rapidly worse. The exact definition of the word "recovery" in this sense is hard to give.

It is diametrically opposed to the teachings of psychology to suppose that a fixed idea, which has persisted for several months or years, can vanish immediately without leaving trace.

The paralysis, or blindness, or anæsthesia, may disappear like magic. But I cannot believe but that there is left an unstable mental state which will persist for at least as long as the more serious symptoms persisted, and which will show itself by abnormal suggestibility, by pains, by nervous attacks, and similar functional disturbances. Such symptoms naturally need not interfere with working capacity, but they must interfere with the comfort of the patient to a considerable degree.

If immediately after an accident a patient could be isolated, and could be cared for by a physician who understood the significance of the symptoms and the best way of treating them, I think we would hear very little of persisting traumatic hysteria. Such ideal conditions, however, are rarely possible. In most cases the patient gets too much sympathy, his complaints are received as though they represented real organic troubles, and instead of being put on a rigid disciplinary routine, he is allowed to follow all the fancies and vagaries of the confirmed nervous invalid. He is thus fed on indulgence and suggestion, which is the food on which hysteria waxes fat. Litigation is often quoted as being the real cause of hysteria. It has never been so in any case that I have seen. Without any exception symptoms of hysteria have appeared before any question of litigation could arise. The question of damages naturally precludes proper treatment, as isolation is not possible when court questions are pending; and, by rehearsing to lawyers and to himself his symptoms, the patient's own miserable condition is kept constantly before his mind, and forms the most potent of all suggesting influences. I believe that it is practically impossible for any one to get well from this disease as long as money questions are at stake, and that the longer such questions are undecided the more the symptoms tend to permanency, and the less probable it becomes that they will ever disappear. But this is a very different thing from

maintaining that the money question is the primary cause, or that the symptoms will immediately disappear on the receipt of damages. That they do not disappear on such receipt is proved by some of the cases quoted. Theoretically the prognosis is better according as to whether after settlement the indications of rational treatment can be carried out or not. These indications are isolation, withdrawal of injurious suggesting influences, and counter suggestion. Hypnotism is sometimes useful.

Indirect suggestion in the treatment of hysteria consists in various devices which shall have the object of proving to the patient that he is not as badly off as he thinks he is. Thus walking machines and massage and passive movements, forcing the patient to stand and to take steps by himself, repeated day after day, eventually prove to the patient that he is not paralyzed. Electricity from constant application to anæsthetic areas brings about a return of sensibility. By similar procedures, defects in other special sense functions, and fixed ideas, can gradually be removed. It is needless to say that in many cases treatment is tedious and exasperating.

It was said that with proper treatment the prognosis was better theoretically, because as a matter of fact such treatment is rarely undertaken. I have never heard of a litigated case of traumatic hysteria being treated by isolation and suggestion, which is the only rational treatment. But treatment by a physician is not, in my opinion, essential to recovery. I am very much inclined to believe that a man, especially if he be poor and a workingman, may get the suggestions requisite for his recovery at his own fireside. His family or his wife, when the suit is over, see themselves not only minus a breadwinner, but also burdened with an invalid. Then they begin to inquire if the patient is really as ill as they thought he had been. The natural vagaries of hysteria feed their growing suspicions. They observe on many occasions the patient doing unconsciously what he would maintain he could not do if asked to do. He might be seen to walk when no one is looking, or help himself with an arm in which every movement was supposed to cause excruciating pain. So that finally the wife comes to believe that there is more or less shamming going on. If she is a woman of vigor and daring, the patient's recovery is not far off. For she would supply to him, either by anger or by appeals to his better nature, the very suggestions which would soon work a recovery.

From all points of view hysteria is a very troublesome affection to deal with. One has to handle the families of hysterical patients with gloves. They are very loath to acknowledge that a relative of theirs can walk but won't, can see, although he thinks himself blind, or has no organic basis for the exaggerated symptoms he presents. They want medicines to be administered, they rebel at the suggestion of isolation, and they soon tire of a doctor who fails to cure. On the witness stand also, hysteria offers many perplexities to the expert. With a full desire to be fair, the medical witness if he is for the plaintiff, has difficulty in presenting his statement in a way to convince the jury that the plaintiff, although he really has nothing the matter with him, is a sick man and not an impostor. When, on the other hand, the medical witness is retained by the defendant, the jury is prone to discredit testimony which maintains that physical deformities can depend merely on idea; for the plaintiff is generally brought to court and is almost sure to present the acme of all the symptoms he has ever had. The hopes for fair settlement are almost none, when, as often happens, the medical experts have failed to recognize the nature of the disease, and testify to all manner of impossible organic conditions.

4 West Fiftieth Street

INFANTILE TYPHOID FEVER.*

By AUGUST ADRIAN STRASSER, M.D.

ARLINGTON, N. J.

The reasons for submitting the following critical study of cases of "Infantile Typhoid Fever" are their comparative novelty and interest and their alleged infrequency of occurrence. In one case the diagnosis was corroborated by bacteriological investigation; in the other, although the Widal test was negative the first time, the clinical manifestations of the disease were beyond dispute, and personally I have no doubt that one week later another specimen would have produced the typical Widal reaction.

Case I.—Elsie M., æt. nineteen months. I had been called to the patient at various times before to treat her for short attacks of subacute bronchitis which seemed to yield readily to the usual remedies. On September 3, 1898, I was called again and found the child very fretful, with a rapid and bounding pulse, a rectal temperature of 103° F., and an anxious facial expression due to dyspnœa. Thick mucous râles could be heard over the back and front of the chest, especially over the bifurcation of the bronchi; bronchial breathing was present over the left lung. There was constipation. The child was put to bed, the bowels were opened with calomel in broken doses, an ice-bag was put to the head, a slight counter-irritant and a cotton jacket were applied to the chest, and an expectorant was given. These seemed to relieve her immediate symptoms, for she was very much better the next day, but to judge from what appeared later, this must have been the period of invasion of the disease.

The following day the fever rose to 105° F. The patient was a little brighter, but far from well in her actions. She was now given an antipyretic and stimulants, and these seemed to ease her still more. The bowels had moved freely after the calomel, but were again constipated after the third day.

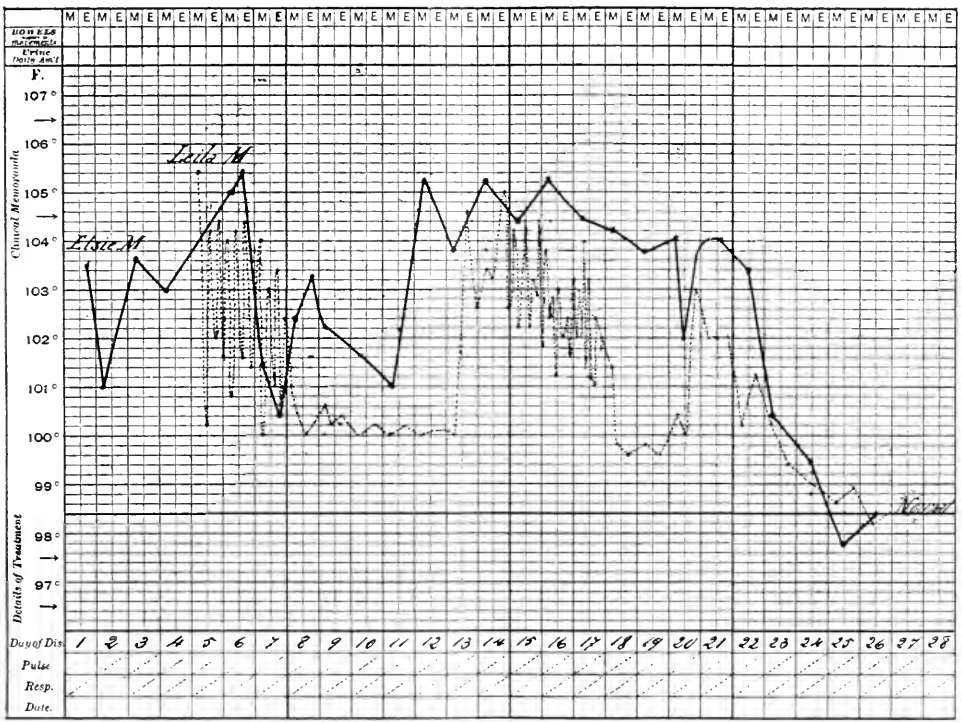
On the morning of the sixth day she was very much worse; temperature, 105°; pulse, 140; respiration, 60. The lung symptoms continued to predominate; there were coarse râles and dulness on percussion over the left lung. She had a slight convulsion from the high temperature, and accordingly I set myself to bring this down. I used a coal-tar antipyretic with brandy ℥ss. and creosote (℥. ½) every hour. After the first hour the temperature fell to 104°, the pulse became easier, and the breathing seemed fuller and freer. In the evening there was little change. The temperature was 105° again, and the respirations were short and seemed only inspiratory. I then started in upon cold baths, much to the parents' alarm; but even after the first one the good effects became apparent, so that under my instructions, and following the guidance of a clinical thermometer, they gave two more during the night.

Early the next morning the temperature was 101.2°; the cough and lung symptoms were unchanged, but the extremities were cold. That was an indication for stimulation; the use of strychnine and nitroglycerin, the interdiction of the cold baths, and the application of hot-water bottles to the feet brought her over this critical point. I had seen no change in her condition and physical signs for a week now, and I was at a loss how to account for a pneumonia of that character. There was no sign of resolution anywhere in the lungs. She now had a fairly constant temperature, hovering around 102° to 103°; the bowels moved regularly once a day. I kept on with stimulation and looked well after careful and

*Read at a meeting of the District Medical Society of Hudson Co., N. J.

systematic feeding. Up to the end of the second week there was not another symptom manifest to the most careful scrutiny, and my notes state distinctly that there was everything to rule out typhoid—no abdominal tenderness, no ileo-cæcal gurgle, no rose rash, no ugly tongue, no diarrhœa, no obstinate constipation; just the cough, the fever, and the emaciation. On the fourteenth day of the disease, I asked a colleague to see the patient with me, and he unhesitatingly pronounced the disease pneumonia. At last, on the eighteenth day, there appeared a most beautiful crop of rose spots. The picture was clear now. Intestinal antisepsis was my first endeavor, and the progress of the disease after that had nothing eventful or atypical in it. A Widal test on the eighteenth day gave a positive reaction.

uranalysis revealed no kidney lesion. A few days later the chest symptoms assumed a pneumonic character; there was rapid, shallow breathing, crepitant râles were audible over the upper lobe of the left lung, there were also friction sounds, but no change in the percussion note. The spleen was decidedly enlarged. The temperature took an erratic course; at first it was very high and accompanied by nervous phenomena, threatening eclampsia momentarily, and could be controlled only by immersion and friction in cool baths; each one of these had the salutary effect of depressing the temperature, quieting the heart, and sending the child to sleep. Here, too, the visible improvement after each bath made converts of her attendants. As the baths were too wearing upon her nurse, I substituted with equally good results the use of the cold trunk pack. Of course,



Case II.—Leila Math, æt. sixteen months. The diagnosis in this case was not corroborated by bacteriological tests, but I think you will agree with me that the course and clinical picture is that of enteric fever. I was called to see the child, who was suffering from a subacute bronchitis; she also had vomiting, anorexia, and fretfulness. The temperature was 103°, and there was a slight cough together with some roughened respiration. The child seemed to improve with the medication given her for a few days, except that the temperature rose every evening, very little, but appreciably. She was given quinine in two-grain doses every three hours in addition to an expectorant.

Now, however, although the chest symptoms had not changed, there were tenderness of the abdomen and tympanites, and constipation, not relieved by calomel or castor oil, so that daily enemata had to be given. She vomited occasionally; stimulation by means of whiskey, digitalis, ammonium carbonate, and strychnine was not spared. Food, liquid and predigested, when necessary, was given her freely. The bronchopneumonia still overshadowed every other symptom for five days, during which period the temperature never rose above 100.5°. This covers the second week of the disease. On the thirteenth day, there was a sudden change in the phenomena. I found a violent stomatitis, diarrhœa with ochre-colored, vilely smelling fæces, iliac tenderness, sordes on the lips and teeth, but no rose spots. There was little delirium, but a steady movement of the temperature downward in irregular step-like drops. With a slight but well defined relapse on the twentieth day, the disease ran henceforth the usual course of typhoid fever, and even the violent hunger of convalescence that follows typhoid fever in adults so often was seen in this case. Aside from quinine and salol she had

no other medication. The lung symptoms cleared up before the seventeenth day and did not show the slightest recurrence.

It is interesting to compare this case with Bryant's.[1] His patient, twenty-one months old, died after a febrile attack of three to four weeks' duration. During the time the child was in the hospital there was no eruption, but an enlarged spleen and a bronchopneumonia. Shortly before death, the blood gave a smart Widal reaction in five-per-cent. solution. At the autopsy no lesion of any kind was found in the intestine. There was a septic bronchopneumonia with enlargement of the mesenteric glands. Cultures from these glands yielded almost pure cultures of bacillus typhosus. A brother and a sister of this patient were admitted to the hospital at the same time suffering from typhoid fever.

These are the cases as I saw them, and now let us go into them a little more critically.

The history of typhoid fever in childhood is far from a threadbare subject. Prior to 1840 it was universally held that this disease never attacked children. Abercrombie, it is true, found typhoid lesions in the intestines of six and seven months' old children (in 1817), Earle[2] and Characlay in 1840 published a case in an eight days old child. Stowell,[3] in his fine article, states that Gerhardt goes farther back in reporting an eight months' fœtus born on the seventh day of its mother's fever. This infant had vomiting, roseola, diarrhœa, and large spleen, but recovered in thirty-eight days. Eberth demonstrated typical bacillus typhosus in organs of four fœtuses aborted by mothers having typhoid fever; eight fœtuses from mothers not ill with typhoid did not show the bacilli.

Of later years the more careful study and classification of malarias and forms of enteritis tended to increase the numbers of typhoids, in differentiating them from the so-called and misnamed typho-malarial troubles; or, as Hare[4] says, "At first sight it would appear that it is more common, but this is only because it was not recognized and recorded. Typhoid fever is by no means as rare as has been supposed. . . . Such a thing as 'simple catarrhal fever' does not exist as an entity, but this term covers a multitude of diagnostic sins." He also points out the fact that Henoch saw nearly four hundred cases, and Ashbey and Wright say that "children and young people are more susceptible to typhoid than adults," but they also say that "it is not common in children under three years of age." On the contrary, Northrup[5] claims that typhoid is extremely rare in children; that the records of children's hospitals show that not a single case had been seen in years; not a case in twenty years in the New York Foundling Hospital; he found in four hundred cases of typhoid in the Stamford epidemic only four cases in infants ranging from thirteen to twenty-two months. And writing about the same epidemic Pierson[6] states that "statistics show that sporadic typhoid is almost unheard of in children under three years of age." To the contrary notwithstanding, Forchheimer[7] reported seventy cases in an epidemic in 1888.

Concerning the etiology of the disease it is scarcely necessary to enlarge upon the subject. *Nihil a nihilo* is still the rule; and given the germ, however introduced, and a favorable nidus, and the disease is established. Both of the cases I detailed above were traceable; the first to infection from ground water in the Bronx Borough section of New York; the other by infection from a common drinking cup in a Newark department store at the time when there was a small epidemic in that city.

As to symptomatology: One must have a great deal of patience with a physician attending a case of typhoid fever. The disease manifests itself in such Protean forms, masquerades so often in other's shapes, that we must be charitable if he refuses to commit himself until one of the symptoms fills out the line of his reasoning. In children especially we must be warned that chest, nerve, and brain symptoms constantly hide the real underlying disease and may remain intense enough to befog the most alert man. As Hare[8] says truly, "At the present time the diagnosis of typhoid fever in children must rest largely upon the chance development of the characteristic rash and enlarged spleen, and more than all upon the Widal test; for the moderation in all symptoms so characteristic of the affection in childhood and the fact that a swollen spleen and liver and a coated tongue with fever are so commonly met with in various children's ailments make an absolute diagnosis in many instances, without this test, almost impossible." In my own cases and in one case under my immediate care in hospital service, the symptoms were very atypical until the end of second week; this is also the conclusion of Wilson and Unger. (Earle.[9]) But Earle says that he has found very little difference between symptoms in children and adults.

The symptoms run about as follows: there are very few prodromata; incubation is not noticeable by any changes in action; in infants headache is not noticed, but in older children it may be intense; both are liable to initial convulsions. The fever is usually the cause for anxiety and the call for the doctor; it runs a wide range and usually is more or less erratic, although somewhat conforming to a fairly typical typhoid curve. The state of the bowels is also of no diagnostic value. Diarrhœa and obstipation are about as frequent here for the first two weeks as they would be in any fever or chest disease. "Bronchitis is common, but seems to remain long in the congestive stage, free expectoration being rare." (Stowell.[10]) In the case detailed above there was at no time real epistaxis, although in the hospital case I mentioned it was quite a feature; and Pierson[11] states that "Epistaxis is more frequent in children than in adults."

The tongue is not characteristic; rose spots are good signs, but appear about in the same proportion as in adult cases. There may be some suppression of urine, for which liberal use of boiled water or lemonade are the best remedies. Concerning the splenic enlargement, while Stowell says it is not common, Earle finds it in seventy per cent. of cases in children.

Hemorrhages and perforations are rare, and this I can emphasize inasmuch as this same hospital case had a relapse because he ate bananas surreptitously smuggled to him, but no evil effects in the shape of hemorrhages or perforations followed.

The main symptom at first (and this is very often true of the adult as well) is the subacute bronchial inflammation due to the excretion of the Eberth bacillus from the bronchi (Noyes[12]), and in children this amounts to the main disease for the first few weeks.

As for differentiation, typhoid may be mistaken for malaria, gastroenteritis, bronchopneumonia, tuberculosis or meningitis (Noyes,[13] Bond[14]), and we must agree with C. L. Greene[15] that its differentiation "is not always easy and is never to be made with certainty before the end of the first five to ten days after the onset of the fever," and he claims that this conservatism is "due to the chastening effect of frequent autopsies and the growth of caution in diagnosis which results from a large clinical experience."

From the prognostic standpoint it is difficult to add anything to a subject when Jacobi[16] hath spoken.

According to him, the dangers of typhoid in children arise "(1) from the originally feeble condition of children; especially if there is any anæmia from chronic intestinal disorders or respiratory ailments (chronic bronchitis or emphysema) or cardiac disabilities; (2) from the amount of toxæmia; (3) possible cardiac failure; (4) hyperpyrexia; (5) the consecutive conditions such as diarrhœa, hemorrhage, perforations and peritonitis or ulcerative endocarditis; and (6) the sequelæ, nephritis and meningitis," to which idiocy can be traced at times. Yet in spite of these rocks in the channel, Noyes concludes that in children convalescence is more rapid than in adults; the mortality is less, and abortive cases are frequent, a view with which I am in entire accord.

As to treatment, it would be presumption to claim to teach you anything; all I can do to fill out this paper is to give you a resume of my own armamentarium and to mention a few of the latest observations of others.

There can be no quarreling with the statement that the use of a combination of a modified Brand method and a modified Woodbridge or Thistle method is the ideal form of treatment. No one who has had any experience with the use of the cold bath, cold packs, or alcohol sponge baths will deny that the effect of them is unique. The temperature can be lowered almost at will; nervous symptoms disappear; lungs and heart act freely and are braced, for it is a tonic, and I have seen adults and youths anxiously begging for another bath when they began to feel uncomfortable. In children the terrors of a full bath can be much mitigated by the use of the cold trunk pack frequently and rapidly changed. And likewise a glance at the pathology shows us that in a modified method of intestinal antisepsis we have another means of combating other symptoms; we can control the toxæmia, guard against perforations, aid the stomatitis and to a slight extent provide a prophylactic for the attendants. In fact I agree with Yeo[17] when he says "the practitioner who, in the face of the evidence that has recently accumulated, neglects to take measures to promote intestinal antisepsis in typhoid incurs a very grave responsibility."

Acting upon these principles, this is one method of treating typhoid fever. The prime requisite, of course, is an intelligent nurse, and though I am well aware that typhoid is a self-limited disease, I am also equally certain that if an early diagnosis can be made so much more chance is there of aborting it or at least so modifying it that, instead of running the usual four to six weeks' course, it can be cured in two to two and one-half weeks, and true Eberth's bacillus typhoid too.

So then, with an intelligent nurse and a clinical thermometer, when the temperature reaches 102.5° or 103°; when there is great nervous irritability threatening convulsions; when there is severe headache, then is the time for the cold bath or pack. For the latter do not use wool or flannel; use muslin or linen lightly wrung out of water at 60° to 50° and quickly slung around the trunk from armpits to thighs and then wrap child up in a blanket; and douse this every five minutes, according to the height of the temperature, carefully watching the heart and giving whiskey and applying heat if the extremities are cold or there is the slightest sign of collapse, these measures will and must bring the temperature down. Repeat in three hours if necessary.

After my good results with baths and the poor results often reported with antipyretics, I look upon them askance. If for any reason, however, baths or packs cannot be used, be it because of the objections of some parents or fear that a nurse will do more harm than good by a careless method, there can be no objection to the careful use of antipyretics. Burney Yeo's method, the use of quinine and chlorine-water mixture, is very efficient; creosote and carbolic acid also act both as antipyretics and antiseptics.

As to other medication individual preference will guide you. Salol is trustworthy and efficient; in the diarrhœas, the various bismuth preparations are best—eudoxine, β-naphthol, subgallate and subnitrate (best when there is no vomiting). If constipation is the feature, calomel, which not only unloads the liver of nature's antiseptic, the bile, but, when broken up, is an antiseptic itself of the best. When there is perforation or even slight show of hemorrhage in the stool, turpentine is the sheet anchor internally, and for the sometimes very distressing meteorism in the form of stupes or in enemata it is very comforting. For this last condition, Jacobi recommends ice-water enemata to make the paralyzed bowels react, and even sanctions puncture of the distended intestinal wall by a hypodermic needle; but he also warns against its dangers, reporting the occurrence of fatal peritonitis therefrom.

Toward the end of the second week, the so-called Woodbridge formula No. 3 is very efficient, but must be carefully and freshly made up; for I have seen in an adult a full dozen capsules, shaped as made, with only the gelatin covering gone, pass from the anus of a patient who had had no solid food for three weeks for fear of perforation!

Of course, rest in bed, the use of fluid food varied as much as possible, milk, malted milk, peptonized milk, whey, kumyss, soups, strained gruels, clam or oyster broth, ice cream, if made by careful hands, are all needlessly mentioned. Contrary to Earle, I do not think it good policy to give a tonic during the course of the disease. The digestive apparatus has all it can do to absorb food to change into antitoxins, and my opinion is that, when these have at last won the upper hand, then is the time to help nature reconstruct—that is the time for tonics.

Horton Smith[18] points out the necessity of as much care in handling the urine as the fæces of typhoid fever cases. He found that, in twenty-five per cent. of cases, the urine contained the bacilli; in five per cent. in such numbers as to render the urine turbid. They are nearly always in pure culture. Urotropin 10-grain doses act as a prophylactic for the attendants as well as for the patient. The urine must be carefully removed and the vessel antisepticized thoroughly after its use.

It is hardly in the province of a general practitioner to speak of operative methods in intestinal hemorrhages or perforations, yet it is good to know that the former let-alone policy must no longer be followed, and the surgeon can still try to save the patient from the resultant violent peritonitis. At this point a warning word must also be spoken against the use of the ordinary ergot preparations for hypodermic injections; the bleb goes into ulceration sooner after this than any other medication, and pyemia may follow, and Jacobi says he has seen such many times. I have only seen the severely painful and swollen arm following such an injection. The arm healed after cicatrization, but was a lesson in possibilities.

Convalescence once established must not be retarded, and solid or semi-solid food not withheld too long. This is a hard task when one has to combat the ravenous appetites most convalescents exhibit. But "make haste slowly" is the best watchword. This is the best time for tonics: not necessarily iron, but good stimulants to metabolism. Nux vomica, quinine, gentian, pepsin, hydrochloric acid, are very useful; I usually use with good results a bone-

marrow extract and some good port for burgundy wines. This usually brings back all that was lost by the disease and tends to strengthen the patient materially.

I cannot say I have added anything new to the clinical aspect or the treatment of the disease, still as a resumé it may have been of interest, and I hope will evoke discussion and elucidation of other methods and an expression as to the frequency of occurrence of similar cases in the practice of others. If differentiation can be simplified I should like to learn how, and I hope to learn whether others encountered similar difficulties and how they mastered them.

A SERIES OF MASTOID OPERATIONS.

By CHARLES H. MAY, M.D.,

NEW YORK.

CHIEF OF CLINIC AND INSTRUCTOR IN OPHTHALMOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT, COLUMBIA UNIVERSITY; ADJUNCT OPHTHALMIC AND AURAL SURGEON, MT. SINAI HOSPITAL, NEW YORK.

THE following are the histories, with comments, of a series of mastoid operations, performed during a short service in the spring of 1900, and comprising both ward and private patients. They illustrate well what Schwartze and others have pointed out that in a great many cases one cannot be certain of the exact findings, even when the indications for opening the mastoid are pronounced.

Chronic Purulent Inflammation of the Middle Ear; Chronic Mastoiditis; Cerebral Abscess (Temporo-Sphenoidal Lobe).—M. B., female, thirty-eight years old, admitted January 10, 1900.

History.—Two years ago had earache and discharge from left ear. One year ago, discharge ceased, and the patient was well until two weeks ago, when there was a return of earache, but no discharge, though (according to the family physician's statement) there was a perforation of the drum membrane; no vomiting, chills, fever, constipation, polyuria, or incontinence of urine or faces. Yesterday, after a period of excitement, during which the patient screamed and moaned, she became stupid.

Examination on Admission.—Pulse 60, respiration 20, temperature 99.2°. Patient in semi-comatose condition. There is marked tenderness upon pressure over the left mastoid region, but no swelling or redness; also otitis externa and chronic purulent inflammation of the middle ear of the left side. Ophthalmoscopic examination reveals bilateral optic neuritis, more marked on the left side. Pupils are contracted, but react to light. The patient was prepared for immediate operation.

Operation.—Chloroform anæsthesia, changed to ether. The usual post-auricular incision was made over the mastoid. No change in periosteum; the latter was incised and pushed back. The bone was chiseled into; beyond being very hard, it showed no pathological changes. The antrum, situated at a depth of three-quarters of an inch, presented nothing abnormal. The sinus was not exposed; the surrounding bone appeared normal. The tip of the mastoid was exposed and opened, but was found normal.

The upper angle of the incision over the mastoid was continued upward about one and a half inches, and the bone laid bare. A piece of bone about one and a quarter inches in diameter was removed in the situation of the temporo-sphenoidal lobe. The dura was congested, but otherwise normal. An aspirating needle was thrust in a direction forward and inward, at an angle of about forty-five degrees; after passing to a depth of about one and a quarter inches, very foul-smelling pus was withdrawn. The dura and brain were opened in this direction, and about a drachm of pus of the same character escaped, making about two drachms in all. The brain tissue surrounding the abscess cavity was necrotic, and particles escaped with the pus. Light probing showed the cavity to extend inward about two inches. Some of the necrotic brain tissue was cut away with scissors, and then a drainage-tube and gauze packing were inserted into the abscess cavity. The scalp wound was partly closed by sutures, and the mastoid wound packed with gauze and left open; dry dressing and bandage.

There was no change whatever in the patient's condition during the operation. After the operation, the patient became very restless; morphine was administered hypodermically. Pulse became slow and more irregular. The muscles of the left lower extremity were contracted and rigid; divergent strabismus. Strychnine hypodermically. At 2.30 A.M., pulse 80, respiration 36, temperature 102°, breathing stertorous. Died at 3.45 A.M.

Post-mortem Examination (Through Wound).—Wound enlarged; an abscess cavity size of large walnut was found in left temporo-sphenoidal lobe. This contained some thick, greenish, foul-smelling pus. The wall was lined by purulent fibrin. The abscess was encapsulated by a wall about one-third cm. thick. No perforation into ventricle; no signs of meningitis. The left hemisphere was removed and examined, but the right was merely aspirated (permission to perform an autopsy having been refused); no abscess found on right side. The dura was not adherent in the situation of the tegmen tympani; on removing the latter, the attic was found full of light-colored pus and cholesteatomatous masses.

In this case, the brain abscess was correctly located and promptly evacuated; but the opportunity for operation came too late. In the absence of complicating cerebral conditions, it is highly probable that the operation, if it had been performed at an earlier period, would have been successful in saving the life of the patient.

Chronic Purulent Inflammation of the Middle Ear; Acute Purulent Mastoiditis.—S. K., male, eighteen months old, admitted January 15, 1900.

History.—Four months ago, swelling, redness, and tenderness appeared over the right mastoid region. Paracentesis of right drum-membrane was performed; this was followed by a discharge of pus, which continued eight days; during this period the ear was irrigated with solution of boric acid. At the end of the week there was a cessation of discharge. For about two weeks the child was well, having no otorrhœa, nor tenderness over the mastoid. A week ago, there appeared again a purulent discharge from the ear; this was accompanied by redness and swelling around the ear and over the mastoid, and extreme tenderness over the latter

area: accompanying these symptoms there was fever; no vomiting or convulsions.

Examination on Admission.—Pulse 134, respiration 30, temperature 101.6°. A very red œdematous and fluctuating swelling occupies the right mastoid and post-auricular regions; there is swelling and œdema of the right auricle. The external auditory canal is swollen and reddened; the right drum-membrane presents a perforation, and the canal is partly filled with purulent discharge.

Operation.—Chloroform anæsthesia. Upon making the usual incision behind and parallel with the attachment of the auricle, there was an escape of a large quantity of pus which had been retained beneath the periosteum. The bone of this region was very soft and necrotic, and the mastoid filled with pus. All diseased bone having been removed with the sharp curette, the upper and lower angles of the incision were closed with silk sutures, the wound packed, and a dry dressing applied.

February 10th, the day after the operation, the temperature was normal; it remained so throughout an uneventful recovery; very slight discharge from external ear; wound healed. Discharged cured.

This case proved to be, as was expected from the first, one of ordinary mastoid empyema, in which both operation and after-treatment were simple.

Chronic Purulent Inflammation of the Middle Ear; Subperiosteal Abscess.—H. J., female, four and a half months old; admitted January 15, 1900.

History.—A purulent discharge from both ears was noticed about four weeks after birth. As a result of treatment, the discharge ceased temporarily, but reappeared shortly after. Discharge had been profuse, particularly from right ear. Three days ago, the patient presented tenderness, redness, and swelling over the right mastoid area. Since this morning there has been no discharge from the right ear; for the past two days none from the left ear.

Examination on Admission.—Pulse 110, respiration 30, temperature 100.2°. Right auricle stands out prominently, and there is diffuse post-auricular swelling, with redness and fluctuation. There is great tenderness over this area. Right ear presents a perforation of the drum membrane and a slight purulent discharge. No bulging or swelling of the walls of the external auditory canal.

Operation.—Chloroform anæsthesia. Usual post-auricular incision. Skin and tissues beneath very œdematous. After incision, there was an escape of a large quantity of pus. Periosteum thickened. Examination of the bone of mastoid region showed this to be healthy. The muscular attachments at the tip were pushed back so as to expose the latter, which was also found to be healthy. The mastoid was not opened. The day following the operation there was facial paralysis of the right side.

January 24th. Otorrhœa continues. The post-auricular wound has healed completely. Facial paralysis slightly improved.

In the preceding instance, the post-auricular abscess was apparently an independent lesion; there was no evidence of any connection with a lesion of the mastoid, nor any signs of extension along the posterior wall of the external canal, nor relationship to the purulent process in the middle ear. In an older and more robust individual, the indication for the performance of the radical operation or the Stacke-Schwartze procedure would have been evident; but the child's general condition was such that only the urgent indication could be considered. The facial paralysis was due to caries in the middle ear, and could not have been caused by the operation. The child was seen several months later; at that time there was still slight facial paralysis.

Chronic Purulent Inflammation of the Middle Ear; Caries of the Ossicles; Chronic Mastoiditis.—S. S., male; four years old; admitted January 23, 1900.

History.—The disease of the right ear dates back thirteen months. At that time it began with pain accompanied by fever. Shortly after, there was a discharge of pus which continued until a week before admission; then it became less in amount, while pain in the ear and neighboring region increased, and marked tenderness over the mastoid region was complained of.

Examination on Admission.—Tenderness and œdema pain over the tip of the right mastoid. Deep-seated in right ear but none in the mastoid region. Stiffness of neck. Enlarged glands at tip of mastoid and in neck. The walls of the right auditory canal are swollen so that the drum-membrane cannot be seen. Discharge from ear purulent, but not offensive. Pulse 90, respiration 20, temperature 101.4°. Ordered irrigations of canal, and hot-water bag to ear.

January 25th. Pulse, respiration, and temperature normal. Prepared for operation.

Operation.—Ether anæsthesia. Usual post-auricular incision over the mastoid, about one and one-half inches in length. Periosteum exposed, found normal, incised, and pushed back. The bone appeared normal. An opening was made with gouge; superficially the bone was healthy, but more deeply, in the region of the antrum, it was found carious and was removed. The antrum was exposed. The bony posterior wall of the canal was next removed with bone forceps and chisel. The malleus and incus were found carious, and were excised. The attachment of the auricle was incised and the flaps thus formed united to the edges of the skin of the mastoid incision. The edges of the mastoid wound were then drawn together with silk sutures, the lower angle being left open and packed for drainage. The cavity made in the mastoid was packed through external canal. Dry dressing and bandage.

February 14th. General condition has been very good since operation. Mastoid healed by primary union. There is now no discharge from the ear. Cured.

This case was one in which the indications for the Stacke operation were pronounced, and in which this procedure effected a cure not only of the mastoiditis, but of the purulent inflammation of the middle ear. The healing process was very rapid, and within three weeks the boy was discharged from the hospital as cured, and required no further attention. Hearing on this side, on date of discharge from the hospital, was 18-24. There was no tenderness over the antrum, in which situation carious bone was found. On the other hand, the tip of the mastoid, which was exceedingly tender upon pressure before operation, was found perfectly healthy.

Chronic Purulent Inflammation of the Middle Ear; Chronic Mastoiditis; Acute General Miliary Tuberculosis; Tubercular Meningitis.—L. K., male, six years old; admitted February 3, 1900.

History.—Six months ago had pain in right ear, accompanied by some fever, and followed by purulent foul-smelling discharge. Ear has been under treatment (irrigations). Eight days ago began to have severe and constant pain in and about the right ear, also fever and vomiting. These symptoms have persisted and have become more marked. The discharge from the ear continues. There have been no muscular twitchings nor convulsions.

Examination on Admission.—Right ear: Canal normal, filled with purulent, offensive discharge. There is a large perforation in the drum-membrane. No tenderness over the region of the mastoid, nor over any part of the cranium; no rigidity of neck.

Left ear: Negative. Eyes: Pupils and muscles normal; the fundus of both sides much pigmented and discs are pale and waxy (atypical pigment degeneration of the retinæ). Pulse 118, respiration 28, temperature 102.8°. Examination of viscera negative. No œdema of legs. Reflexes normal. Pulse irregular and intermittent.

February 4th. Patient unable to urinate; hot-water enema was given and was effectual. Ears were irrigated with warm boracic acid solution; slept all night. Mental condition good, and child does not complain of headache or pain. Considerable foul, purulent discharge from the right ear. During the evening the patient became restless and vomited. Pulse 90 to 122, respiration 22 to 26, temperature 103°. Profuse perspiration.

February 5th. General condition less favorable; severe headache. Patient seems stupid. Discharge from ear continues profuse. During the night the patient became very restless. Pulse weak, irregular, and intermittent. In the morning, the temperature fell from 101.4° to 97.6°, and then rose to 98.8°. Examination of the blood showed leucocytosis (16,400 whites); no plasmodia malariæ.

Operation.—Chloroform anæsthesia, then ether. Usual post-auricular incision. No œdema of skin or deep tissues. Periosteum normal. Bone was exposed and chiseled into; the outer portion was hard and healthy, but in the region of the antrum there was considerable granulation tissue, which was removed with the sharp curette. The posterior wall of the bony auditory canal was removed, exposing the middle ear; malleus and incus absent. No pus was encountered. The incision was extended over the tip of the mastoid, and this portion, though normal, was removed with chisel. Next the sinus was exposed; it appeared healthy; it was opened and bled profusely; then packed. The bone around the sinus was normal. The operation was completed in the usual Stacke-Schwartze manner, the sinus packed through the lower angle of the wound, and the cavity in the mastoid through the external ear. Dry dressing.

February 6th. General condition improved; mental condition good; child does not complain. Reflexes normal. Vomited twice. Eight A.M., temperature 97.8°, pulse 112, respiration 26; at 5 P.M., temperature 103°, pulse 120, respiration 24. No chill or convulsions; profuse sweating. Urine turbid, acid, sp. gr. 1.030, contains albumin; microscopically, pus and epithelial cells, occasional hyalogranular and finely granular casts.

February 7th.—General condition unchanged; no convulsions. Evening rise of temperature to 103.8°. Reflexes unchanged. Mental condition good. Patient has no pain or tenderness anywhere except at site of wound. Strong percussion of skull elicits no tenderness. No rigidity of muscles of neck. Takes very little nourishment.

February 8th. Patient appears emaciated. Tongue moist and slightly coated. Bowels moved by cathartics and enemata. Physical examination of chest, abdomen, and extremities negative. No convulsions. Wound dressed (looks well, packings changed.

February 10th. Patient takes very little nourishment. Wound dressed, some of the stitches removed. Mental condition continues clear. Patient complains of occasional pain in the region of the wound.

February 12th. General condition the same. Mental condition clear. Reflexes normal. Wound dressed, slight discharge. Continues to have evening rises of temperature (103°). Blood examination and culture negative except existence of considerable leucocytosis (22,400 white blood cells).

February 15th. A.M., mental condition clear. Reflexes unchanged. Child somewhat irritable. Wound dressed and found in good condition. At 5 P.M. child began to cry out; right hand contracted; athetoid movements; some loss of power in right upper extremity. There is ankle clonus of both sides, particularly marked on right side. Abdominal and cremasteric reflexes present. Knee-jerk marked on right side. Spasmodic contractures of groups of muscles of right thigh (spasms not marked). In the evening, a lumbar puncture was made between second and third lumbar vertebræ, and about 40 c.c. of slightly turbid fluid removed; this was not followed by any change in the symptoms. The pupils have been equal throughout the disease, and react well to light; no photophobia. There is now marked rigidity of the muscles of the neck.

February 16th. General condition unfavorable. There is dulness of sensation and partial paralysis of right side of face; also partial anæsthesia of right conjunctiva and cornea. Pupils are equal and react to light. Abdominal reflex on right side absent. Pin pricks not promptly perceived in right leg. Ankle clonus and reflexes of lower extremities still present, but not so marked as yesterday. During the night the child uttered shrill cries in sleep. Highest temperature 101.4°. Wound dressed.

February 18th. Both hands contracted; athetoid movements; twitchings of the muscles of the left upper extremity. Later, general tonic contraction, with opisthotonus. Eyes rotated upward and to the right; pupils of equal size and moderately dilated. Convulsion lasting about half a minute, repeated several times during the day. At the end of these attacks there was marked ankle clonus, particularly of right side, and heightened knee-jerks of both sides. Anæsthesia as before. Abdominal reflexes absent on right side. Cremasteric reflexes well marked. Plantar reflex present, more marked on left side. Patient has involuntary micturition.

February 19th. Condition much worse; marked stupor; twitchings on both sides of the body; no pupillary changes. Reflexes are difficult to obtain. Tache cerebrale well marked. There is intermittent rigidity of neck.

February 20th. Stupor persists; occasional contractions of groups of muscles. Reflexes cannot be obtained. There is some pulmonary congestion of both bases. In the evening the child developed stertorous breathing, and the pulmonary congestion became more marked. Marked rigidity. Lumbar puncture not followed by any change in symptoms. Examination of the puncture fluid showed tubercle bacilli.

February 21st. Child continued in comatose condition, and died early in the morning.

The symptoms which this patient presented upon admission to the hospital were obscure as far as they pointed to his systemic affection. The only positive symptoms were those relating to his ear; hence he was placed in the aural service. The finding of tubercle bacilli in the cerebrospinal fluid, as well as other "unofficial" post-mortem evidences (no autopsy was permitted), rendered the diagnosis of acute general miliary tuberculosis positive. It is therefore proper to regard the middle ear and mastoid affections either as incidental lesions or as complications of his general disease; the surgical treatment of these had no effect, of course, upon the progress and termination of the tubercular affection.

Subacute Purulent Inflammation of the Middle Ear; Caries of the Mastoid.—Miss F. M. D., twenty-two years, admitted February 14, 1900.

History.—This patient was discharged from the hospital on February 10th with the diagnosis of sub-

acute purulent inflammation of the middle ear with mastoiditis, condition improved. There has been slight but persistent tenderness over the mastoid antrum, and a slight elevation of temperature every evening (100°).

Examination on Readmission.—Right ear: Large perforation of drum-membrane and slight otorrhœa. No redness or swelling of the walls of the auditory canal. Tenderness on deep pressure over mastoid antrum. No œdema or redness over mastoid. No headache. No general malaise. Temperature normal A. M., 100° P. M.

Operation.—February 15th. Chloroform then ether anæsthesia. An incision about one and one-half inches long, made in usual post-auricular situation No œdema of tissues. Periosteum incised and pushed back; found in normal condition. The bone appeared healthy. After removing the superficial layers with gouge, the mastoid was found carious, soft, congested, and filled with much granulation tissue and pus. The necrotic and granulation tissue was found to extend some distance inward toward the antrum and middle ear, to below the tip of the mastoid, and posteriorly toward the occipital region. The diseased bone was removed with bone forceps and sharp curette until healthy walls were encountered, leaving a cavity about one inch in diameter and three-quarters inch in depth. The removal of diseased bone exposed the lateral sinus surrounded by necrosed tissue; the latter was scraped away. The wound was irrigated and packed. The upper angle of the wound was closed with sutures, the lower angle left open.

March 5th. Patient has improved uninterruptedly; there is still, however, a slight discharge from the ear.

April 1st. The wound has closed entirely. There is no discharge from the middle ear, and the perforation of the drum-membrane has closed. Hearing normal.

This case proved extremely interesting and illustrated how much destruction of tissue could take place with but slight symptoms, and how rapidly such changes could occur. This patient was first seen by the writer, at her home, during the latter part of December, 1899. At that time she had had grippe, and following this, an acute suppurative inflammation of the middle ear, with spontaneous perforation of the drum-membrane. After a few days of pain, headache, moderate rise of temperature, and general malaise, these symptoms subsided, and the patient was apparently recovering, when there occurred some swelling, redness, and tenderness over the mastoid (acute mastoiditis). The writer was prepared to open the mastoid early in January, 1900, but during the morning of the day set for the operation there was a sudden improvement. The discharge from the middle ear became profuse, the temperature dropped to normal, there was a marked diminution of redness, swelling, and tenderness over the mastoid, and in every way there was less indication for operative intervention. Accordingly, the operation was postponed. During the next few days there seemed to be steady improvement, and the patient was up and about, with no other symptoms except otorrhœa, and a very slight tenderness over the mastoid antrum; which symptom was absent at times. Early in February the mastoid tenderness, though slight, was persistent; the patient complained of headache, and there were slight rises of temperature (100°) in the evening. The perforation in the drum-membrane seeming insufficient, this was enlarged (under nitrous oxide), and a small teat of mucous membrane which projected throught the opening was cauterized, so as to remove the obstruction. But these procedures failed to cause any material improvement. Finally, on February 15th, the mastoid was opened, with the result given above.

Chronic Purulent Inflammation of the Middle Ear; Chronic Condensing Mastoiditis; Caries of the Posterior Wall of the Auditory Canal.—Miss C. O., twenty-eight years; admitted February 10, 1900.

History.—Two years ago, the patient was operated upon by the writer for mastoid disease on the same (right) side. At that time she had chronic purulent inflammation of the middle ear, with pain and tenderness over the mastoid. The mastoid was exposed and opened; there was marked eburnation, but no other change in the bone. The pain and tenderness over the mastoid disappeared, but the purulent inflammation of the middle ear has persisted, with rather foul-smelling discharge. For one week she has complained of very severe, shooting pains over the site of the mastoid scar, and there is considerable tenderness over this area. The patient is of a very neurotic temperament. The right auditory canal appears normal. The membrana tympani presents a large perforation through which there is an escape of offensive pus. Just behind this perforation, at the junction of the drum-membrane and canal, there are minute granulations. Pulse, respiration, and temperature normal.

Operation.—February 22d. Ether anæsthesia. Incision made just in front of old scar, behind auricle. Soft tissues, including periosteum, perfectly normal. The bone was attacked with gouge and chisel; it was eburnated and very hard, so that it was removed with difficulty. The region of the antrum was opened, but there was an absence of all cells, and no space corresponding to the antrum could be found. The region of the sinus and that of the tip was explored; the bone was found hard, but otherwise normal. An emissary to the lateral sinus was accidentally opened and bled profusely. Twitching of the right side of the face was thought to have been observed during the operation, but there was no subsequent paralysis of the facial. The posterior wall of the auditory canal was found carious over a small area, and this diseased part was removed, so that a large cavity comprising mastoid opening and middle ear resulted. The wound was packed both from the mastoid wound and the auditory canal.

March 13th. The patient recovered rapidly, the wound healed promptly, and there was no further pain. The otorrhœa has diminished, and the discharge is free from odor.

April 1st. Completely cured. There is no discharge from the middle ear. The cavity in the mastoid is lined with epithelium continued from the auditory canal. A small post-auricular opening has persisted.

This patient presented an example of so-called "nervous" mastoiditis. It is a question whether her severe pain was due to the sclerosing process, or to the caries of the posterior wall of the auditory canal; the latter was exceedingly limited in extent. However, the removal of bone from the mastoid, as well as the excision of the posterior wall of the canal, gave complete relief from pain, as it had done two years previously. The second operation also cured the purulent inflammation of the middle ear.

Acute Suppurative Mastoiditis Bilateral Occurring in the Course of Diphtheria.—H. T., four years old; admitted March 11, 1900.

History.—Four weeks previously, the patient had diphtheria, and developed a purulent inflammation of the middle ear of the right side, with acute mastoiditis. Though his general condition was precarious, the indication for opening the mastoid was urgent. He was operated upon by the writer, and an immense quantity of pus and carious bone removed. He made a good recovery. A week ago,

he developed acute inflammation of the middle ear and acute mastoiditis on the left side. On admission, pulse 144, respiration 32, temperature 101.4°.

Operation.—March 12th. Ether anæsthesia. The usual incision was made behind the left auricle, over the mastoid, the periosteum incised and separated. The bone was apparently normal; but after the gouge had removed the outer layers, the entire mastoid process was found to be carious and its cells filled with pus and granulation tissue. The diseased area involved the entire mastoid including the tip. All the diseased bone was removed with bone forceps and sharp curette and the antrum well exposed. There was free communication with the middle ear. The sinus was not exposed. The wound was packed with gauze; no sutures.

March 25th. A complicating severe enterocolitis gave rise to elevation of temperature (103°) for several days. With this exception, the progress has been favorable and the temperature normal. There is considerable discharge from the mastoid opening, and also from the middle ear.

April 15th. There is no discharge from the middle ear of the right side, and but little on the left. On both sides, the mastoid wound is filling up slowly.

The first operation was performed at the home of the patient. At the time of the operation, he had considerable diphtheritic membrane in the throat and nose, and his condition was serious. The indications for the operation were urgent, and it was performed as soon as possible—at midnight. This operation was remarkable on account of the immense amount of diseased and broken-down bone which had to be removed. There was no diphtheritic infection of the mastoid wound, and rapid improvement set in soon after the operation. In the second operation also (left ear) the amount of destruction was much greater than was indicated by the external evidences of disease previous to operation.

698 Madison Avenue, New York.

THE ZOOLOGICAL DISTRIBUTION OF TUBERCULOSIS.

By WOODS HUTCHINSON, A.M., M.D.,
NEWFIELD, ONEIDA CO., N.Y.

PROFESSOR OF COMPARATIVE PATHOLOGY, UNIVERSITY OF BUFFALO; LECTURER UPON COMPARATIVE PATHOLOGY, BOSTON SCHOOL OF CHIROPATHY; COLLEGE AND POLYCLINIC.

The object of this brief paper is to make a slight contribution to the study of the problem of the factors which determine susceptibility to tuberculous infection. This consists of a preliminary report of my observations in the post-mortem room of the London Zoological Gardens during the winter and spring of 1898–1899. I am deeply indebted to the courtesy of the officers of the Zoological Society and especially to the Vice-Secretary and Prosector, Mr. F. E. Beddard, both for the superb opportunities for pathological study afforded me and for valuable assistance in my work. The report is avowedly preliminary and incomplete, and any conclusions drawn from such a limited number of cases can obviously be only tentative or suggestive, but as the results obtained agree quite closely with the experience of veterinarians among the domestic animals, I thought that a brief statement of them might not be without interest.

I propose to briefly discuss the relative value of three great predisposing factors—race, food, and housing—in animals, in the light of the death records of the Gardens for the past five years, and the results of my own observations in the Prosector's rooms during the past winter and spring.

Taking up, first, the distribution of the malady among the different orders of birds and mammals, then its incidence upon the carnivora and birds of prey, on the one hand, and the ungulates and gallinæ on the other, and finally the difference in its death-rate in animals and birds of the same orders, kept in open cages or unwarmed houses and those kept in houses artificially heated during the greater part of the year.

One word as to the methods of diagnosis of the cases reported upon. The disease in animals is so well marked and so characteristic that not every case has been submitted to a bacteriological examination; type cases both characteristic and doubtful have been selected from time to time, and these have been kindly examined for bacilli by Dr. A. G. Foulerton and Dr. George Newman, and the naked-eye diagnosis checked by the results. "Tubercles" are produced in other diseases, but most of them can be readily distinguished from the "genuine" form upon careful inspection, and comparative pathologists are agreed that at least ninety per cent. of all conditions presenting well-marked "tubercles" in the organs are produced by Koch's bacillus. As illustrating the possibility of separating the pseudo-tuberculoses, I may say that I have found in the present series eleven cases of various forms of these in addition to the forty-seven genuine cases, some of which were quite puzzling at first but most of them clearly recognizable.

The period covered by my report is from October 20, 1898, to May 20, 1899, with the exception of three weeks in March and a week at Christmas time, making six months net. In this time, 213 autopsies were made and recorded, or about sixty per cent. of all the deaths occurring during the time, many of the animals, especially among the reptiles, being either unfit or unavailable for examination, or dead of obvious external causes, which made their remains of no pathologic interest. Of these 213 autopsies recorded, six were upon animals dying by accident and sixteen upon reptiles and fishes which, for the purposes of this paper, are of no value, leaving 191 cases of death in birds and mammals. I may say, however, that a fourth variety of the tubercle bacillus, the reptilian, has been announced by several observers, and that no less than four of the sixteen reptiles presented changes which were suggestive of tuberculosis, two of which were found to contain bacilli resembling the avian form in shape.

Out of these 191 deaths, no less than 47 were caused by a well-marked form of tuberculosis or 24.6 per cent., double the ordinary human rate.

Of the deaths, sixty per cent. were in mammals and forty per cent. in birds, while the proportion of tubercle was almost exactly the same in both. It would of course be absurd to attempt to accurately distribute the percentage of such a small number of deaths among all the different orders of mammals, so I have simply taken five great groups in each and worked out the distribution of the disease in these. These groups have also been chosen with a view to giving a basis for the study of the effects of food upon susceptibility. The results can, I think, best be presented in tabular form.

Family or Race.—It is, I think, fairly clear from the Tables I and II that race or family, as such, or rank of development, has but little direct connection with susceptibility to tuberculosis.

In mammals the highest order, the primates, is by far the most liable per 100 living (Table II), while next to it comes the lowest division, the marsupials. Ungulates and carnivora, which are usually ranked as on about the same level of specialization, are widely separated, the former having six times the death-rate of

the latter. Within the order of the ungulates itself, the most striking contrasts occur, the perissodactyles (odd-toed) being almost completely exempt—even

TABLE I.

	Total Deaths	Deaths from Tuberculosis	Per cent. of Tubercular
Mammals—			
Primates	45	17	37.8
Ungulates	60	5	8.3
Carnivora	21	1	4.8
Rodents	6	1	16.6
Marsupials	22	2	9.1
Birds—

Gallinæ	10	9	50.2
Parrots and toucans	9	2	22.2
Water-fowl and waders	27	5	18.5

horses and asses under domestication, while the artiodactyles (even-toed) are extremely liable. But there are marked differences even among the families of this last sub-order, the pigs being nearly immune while the ruminants are very susceptible; though of these latter the cervidæ are almost exempt, not a single death from tubercle having occured among the forty-one deer in the Gardens during the period covered by this report, while among the thirty-nine antelopes there were three.

Among the birds we find the same confusion of ranks, but in an entirely different order. The highest order listed, the psittaci (Table II) (the passeres were

TABLE II.

	No. Living	Death-Rate per Annum, aged to 6 Months' Average	Death-Rate, aged to 5 Years' Average	Percentage Death-Rate Due to Tubercle.	Deaths by Tubercle per 100 Living.
Mammals—					
Primates	155	58%	60%	37.0%	22
Ungulates (Ruminants)	118	15%	23%	26.0%	6
Carnivora	185	23%	35%	2.7%	1
Rodents	75	16%	85%	3.0%	3
Marsupials	58	70%	45%	15.5%	7
Birds—					
Psittaci	300	6%	14%	7.1%	1
Gallinæ	160	20%	33%	33.3%	11
Raptores	105	24%	54%	11.1%	6
Water-fowls	330	17%	13%	23.0%	3
Struthiones	19	32%	35%	28.5%	12

omitted for reasons of convenience, but their death-rate is extremely low), have the lowest death-rate (1%). The lowest order has next to the highest (10%). The gallinæ and the raptores, which may be compared in relative level with the ungulates and carnivora, have the highest and the third highest death-rates respectively, the difference between them being less than two to one, instead of six to one in the analogous mammalian groups.

The anatinæ (ducks and geese), which lie perhaps lowest of all the carinatæ, have a low death-rate, in marked contrast with that of the highest struthiones (ostriches), their next neighbors in the list.

And while deductions from such a small number of deaths can only be regarded as tentative and, indeed, preliminary, yet the results correspond very closely with those of veterinarian observers for mammals and of Dr. Heinvot, the ornithopathologist of the Berlin Zoological Gardens, who informs me that tubercle is extremely common in grain-eating birds, especially doves and very rare in flesh-eaters and song birds.

Food and Food Habits.—When we arrange our groups of mammals and birds according to their food habits we find what seems to be in the main a real correspondence with their relative death-rates, although there are some curious exceptions (Table III.).

Raptores	"	9.

In this grouping I have classed both the monkeys and the parrots as vegetable feeders, since although both of these receive a certain amount of chopped meat, milk, eggs, insects, etc., yet nine-tenths of their food is vegetable. Indeed, the keepers inform me that among the monkeys only the American species (platyrrhines), who form barely ten per cent. of the whole, receive animal food in any appreciable quantity.

These figures appear to point strongly toward a greatly increased susceptibility to the disease among vegetable feeders and a much reduced liability among meat-eaters, both mammals and birds. And this corresponds closely with the results of veterinary experience, in which cattle, rabbits, and guinea-pigs are highly susceptible; pigs much less so, and dogs, cats, and rats almost immune; hawks, owls, and song-birds slightly susceptible; fowls and turkeys extremely so.

Here again there are, however, serious exceptions to the apparent rule. The horse, ass—indeed all the odd-toed ungulates—the goat and the sheep, all pure vegetable feeders, having marked resisting powers and very seldom becoming infected. Evidently, although food-habits coincide more nearly with the distribution of tubercle than do racial divisions, yet there is some other additional factor involved.

Housing.—The question of the influence of confinement in artificially heated houses or in unwarmed sheds is an extremely difficult one to investigate, on account of the scarcity of fair parallels for purposes of comparison. For the most part only tropical and sub-tropical animals and birds are confined in heated houses, and only temperate or sub-arctic ones in the open sheds or unwarmed buildings, and both of these classes would probably die much more rapidly than they do if their quarters were reversed. On the other hand, it must also be remembered that, in the scarcity of space in the Gardens, animals living practically out of doors may have and often have no more space for exercise or larger sleeping quarters than those in warmed houses, and that some of the older buildings and sheds are worse ventilated and lighted than the modern heated houses; so that even out-door animals may be under as far from ideal conditions as indoor ones.

Temperament and adaptability must also be taken into account. An eagle in an open-air forty-foot cage, for instance, is much more injuriously "confined" than a parrot in a four-foot one in a hot-house.

So that we find the results so conflicting as to re-

clude any positive conclusions. Among mammals we have both the highest (primates) and lowest (carnivora) tuberculosis-rate in highly heated houses. Among birds the highest rate (gallinæ) is in the open air; the next in a moderately heated house (struthiones), and the lowest in the hottest house of all (psittaci). So that, as between orders and families, there is nothing to be deduced from this factor in their environment.

Between members of the same order, however, there are a few suggestive contrasts.

Among the ungulates, as already mentioned, during the past winter, not a single death from tubercle came under my observation, among the forty-one cervidæ and thirty-eight bovidæ kept in open-air houses and sheds, while three occurred among the thirty-nine antelopes in warmed houses. The average life of the inmates of the monkey-house is about twenty months, while the Chinese (tcheli) and Japanese monkeys in the outside cages at each end of the house have already survived thirteen and seven years respectively. They were, of course, picked and hardened specimens to begin with, but they certainly would not have lasted half that time inside the house. Upon one occasion a female companion of a smaller species was placed with the older tcheli and lived happily for nearly four years, when the pair took to quarreling, so that she had to be returned to the house, where she died in six months. Another monkey presented to the Society had lived outdoors in a garden in Islington for seven years, but only survived the monkey-house six months. The few facts available would seem to point decidedly in the direction of the desirability of as little heat and as much fresh air as is reasonably consistent with survival.

A conclusion which both the Superintendent and Assistant Superintendent hold strongly, on the basis of a wide practical experience, and which is supported by the remarkable lowering of the death-rate following the addition of large out-door exercise-cages, open even in winter, in the continental and American zoological gardens. In Cincinnati the death-rate was reduced by this out-door treatment nearly fifty per cent., and in Philadelphia has been lowered to fifteen per cent. per annum, barely one-fourth of the London rate.

It would appear that some influence connected with the food-habits of both mammals and birds exercises an effect more or less constant upon their susceptibility to tuberculosis.

Food-habits may act in at least three different ways. 1. By the food itself becoming the vehicle of infection; 2, by some direct nutritive effect of the food upon the organism, increasing or lowering the vigor; 3, by the securing of the food in a state of nature, involving the attainment and maintenance of varying degrees of vigor and endurance.

The first of these possibilities has, I think, but little practical bearing, for while both classes of food are equally liable to the chance of infection by bacillus-laden dust, air, and fluids, sputum, etc., meat of every sort has the additional possibility of being itself infected—and yet tubercle is nearly twelve times as common in herbivora as in carnivora.

For the second possible effect there is more to be said, as meat is unquestionably more stimulating, more easily digestible, and more nutritious in proportion to its weight than any form of vegetable food.

Moreover, as the interesting experiments of Brouardel have shown, foxes and rats upon a carnivorous diet are almost completely refractory to infection by tubercle; while upon a vegetable diet, although they throve and gained weight, they became more than twice as susceptible. Calves, so long as they live exclusively upon milk, even from tuberculous cows, are almost completely exempt from tuberculosis, only from one in 5,000 to one in 20 000 having been found infected in the German slaughter-house inspection.

An interesting contrast in this respect exists between Old World monkeys and apes (catarrhines) in the Zoological Gardens and the New World monkeys (platyrrhines).

As already mentioned, the former are almost exclusively vegetarian, while the latter receive quite a fair proportion of animal food in the shape of eggs, meal-worms and other grubs or insects, and sparrows, which last they devour with great gusto. And if any of these last courageous little foragers ventures into the house and large cages in search of scraps, he is pursued with astonishing agility and often actually captured.

The reason why this element is included in their diet is that they simply cannot be got to live without it.

It may be nothing more than a coincidence, but of the thirty-five deaths occurring during the six months among the vegetarian catarrhines no less than seventeen were due to tuberculosis, while not one of the ten deaths among the carnivorous platyrrhines was due to this cause. Upon inquiry of both the keeper and of the experienced attendant in the post-mortem room I was assured that in their experience tuberculosis was quite rare among the New World monkeys. And, as the death-rate from all causes among the New World monkeys was slightly in excess of that among the Old World ones (sixty-two per cent. per annum as against fifty-eight per cent.), the discrepancy can hardly be due simply to the surroundings agreeing better with the former than the latter.

And various keepers of experience have assured me that it is only since the introduction of a considerable element of animal food into the diet of anthropoid apes that it has been possible to keep them alive in captivity for more than a short time. The seven years' survival of the celebrated "Sally" at Regents Park is regarded as largely due to her partiality for beef-tea, of which she partook largely, and which is now a regular article of diet with all the anthropoids.

In human tuberculosis, the most successful food-cure which has yet been found is to put the patient upon a diet consisting chiefly, and in some cases exclusively, of broiled beef-steak and hot water; and some form of highly nitrogenous diet is usually insisted upon in the open-air sanatoria. In most of our American sanatoria this diet is strongly insisted upon, and my friend Dr. Tristram Pruen informs me that Walther compels his patients at Nordrach to take large quantities of milk and meat—especially in the form of ham and bacon—and that he finds this diet of the greatest value in his own sanatorium at Cheltenham. Although this diet is by no means confined exclusively to proteids, yet how distinctly carnivorous it is may be judged from the fact that the standard aimed at is the ingestion of the equivalent of *thirteen pints* of milk per day. And this proteid-cramming is regarded as second only in curative influence to the constant open-air life.

This food-effect, however, can only explain a part of the divergencies, for several families of herbivora, the horse, the ass, the goat, have almost as complete an immunity as the carnivora.

In the third factor we find what seems to me far the most important element in the relative immunity of flesh-eaters and that is the resultant habits of life and the vigor and endurance entailed by them. That a carnivorous method of life in the majority of instances demands a higher degree of activity, speed, and endurance than a herbivorous one needs, I think, little demonstration. And where, from any cause this higher degree of vigor and dash has

been acquired by herbivora, then immunity from tuberculosis follows. And as the degree of his vigor and activity is probably best roughly indicated by the size of the heart relative to the body weight I have ventured to arrange my orders and groups again according to this character.

As will be seen, the variations in this regard seem to run more nearly parallel with the distribution of tuberculosis than any other yet suggested, but as I have only been able to find one series of measurements for birds (J. Jones in *Smithsonian Journal*, 1856) and a few scattered ones for mammals, and many of these are based on two or three or even a single specimen, it can merely be regarded as an interesting and suggestive coincidence.

It, however, corresponds quite closely both with the differences between birds and mammals—the former with their larger hearts having an average death-rate by tubercle of six per cent. (per 100 living) as against a mammalian one of nine per cent., and with the contrasts between the carnivora and birds of prey, with their large hearts, and the bovidæ and gallinæ with their small ones. It also harmonizes the curious differences between the horse and deer, and the cattle and antelopes; leaving, however, the sheep with its small heart and low tuberculous death-rate, a marked exception.

TABLE IV

Susceptibility to Tubercle according to Relative Heart Weight.

	Per Cent. of Deaths by Tubercle	Heart Weight	Body Weight
Mammals—			
Primates	22	1	102
Ungulates (Ruminants)	6	1	220
Marsupials	7	1	280 (Opossum)
Carnivora	1	1	90
Equidæ	Very low	1	100
Cervidæ	" "	1	130
Birds—			
Gallinæ	11	1	270 (Turkey)
Raptores	5	1	113 (Vulture)
Water-Fowl	3	1	124 (Duck)
Parrots	1	1	85

In our own species it has been suggested by more than one authority that the size and vigor of the heart was an important element in the predisposition to tuberculosis. Years ago Fothergill declared that the typical consumptive was small of heart and large of lung. The feebleness and rapidity of the pulse in even the earliest stages of phthisis are almost diagnostic. Dr. Pruen informs me that Bodington, the originator, over sixty years ago, of the superb open-air treatment of phthisis, considered the chief problem of the disease to be the weak heart, and devoted his attention more to the strengthening of the heart than to any other factor. And Walther of Nordrach to-day holds almost identical views regarding the state of the heart as chiefly responsible for the failure of the lungs to resist bacillary invasion. Altogether the conclusion to which this preliminary survey of the question of the distribution of tubercle points is that it is a matter of vigor, endurance, and resisting power rather than of race, food, or exposure to infection; and as these powers are usually higher in flesh-eaters than in vegetable feeders, the former possess a marked relative immunity.

Dr. R. T. Hewlett, formerly connected with the Jenner Institute of Preventive Medicine, has quite recently been appointed professor of general pathology and bacteriology at King's College, London.

BIFOCAL LENSES; WHAT AREA SHALL BE DEVOTED TO THE SHORTER FOCUS?

By John E. Weeks, M.D.
New York,
Surgeon New York Eye and Ear Infirmary.

The question of eye glasses for the correction of errors of refraction and for aiding the vision of the old is one of much importance to mankind. Nature has failed to form an organ that perfectly complies with the laws of optics—in approximately seventy-five per cent. of the human race. In order to afford normal, easy vision to this defective seventy-five per cent. of mankind, glasses suitable to the individual should be worn. At the age of forty-two to forty-four years the phase of vision known as presbyopia makes itself manifest, particularly to civilized humanity, and glasses to remove its disadvantages are desirable.

If presbyopia supervenes on an eye of the normal (emmetropic) type, a glass for reading only is required. This is supplied in various forms, and, as but one pair of glasses is required, can be managed without trouble. When the individual who is not emmetropic reaches the presbyopic period, he must have a glass for distance vision possessing a focal distance differing from that required for close work. This means either that he must have two pairs of glasses, necessitating frequent changing, that he must wear a separate "front," or that he must employ bifocal glasses, namely, glasses one part of which is suited for distance and one part for near vision.

Bifocals are said to have been invented by Benjamin Franklin about the year 1770. ("The Complete Works of Benjamin Franklin," edited by John Bigelow, N. Y., 1888.) They consisted of ordinary spectacle lenses that were split in the horizontal diameter. Half a lens of proper principal focal distance for distance vision was put in the upper half, and half of a lens with proper principal focal distance for reading was put in the lower half of the spectacle. Various modifications of this principle have been made from time to time, sometimes with a view to making the lens more elegant in appearance, sometimes to lessen the area of one or the other part for the purpose of extending the field of vision as obtained through one or the other part.

Bifocal lenses, as a rule, occasion much annoyance to the individual who attempts to wear them, particularly at first. They can be worn very comfortably when one is seated or when one is not moving about. The chief trouble experienced in their use is inconvenience occasioned by the blurring, which occurs when objects at a distance of more than two or three feet are seen through the part for reading. A lesser source of annoyance is the dispersion of rays of light that occurs at the line of union of the reading with the distance part of the lens, also by the removal of the optical center of one lens from the optical center of the other lens. Attempts have been made to remove the first of these sources of annoyances by lessening the size of the part of the lens used for close work. If a pair of the bifocal glasses of the Franklin pattern are being worn, walking is rendered quite difficult unless the glasses are very low on the face and the individual bends the head forward. It has been found that by shaping the lower segment so that the field for distance vision is not cut off at the sides (see Figs. 2 and 3) less annoyance is occasioned. Small oval discs have been substituted for the crescent-shaped slips; these leave the sides free, and they can be placed on the distance lens 1½ to 3 mm. above the margin of the lens, permitting of limited distance vision all

around the portion used for reading. This is probably the form best suited for bifocal glasses. The size of the disc should be carefully determined. Heretofore this has apparently not been done.

The ordinary proper reading distance is thirteen to fourteen inches from the eye. The fovea centralis is fully covered by the image of an object, placed at this distance, of about 9 mm. (⅜ in.) in diameter. Outside of this the distinctness of the image gradually diminishes, so that at the periphery of an area of 5 cm. (2 in.) in diameter, long primer type and even pica cannot be distinguished. To see distinctly over a wider area necessitates a movement of the eyes. If now we place on the distance lenses a disc for reading that affords a reading field sufficiently large to cover a page of the ordinary book in the horizontal and one-half of a page in the vertical meridian, the necessary requirement for reading and for close work will have been obtained.

Segments of circles ordinarily employed measure from 20 to 30 mm. in their horizontal diameters and 13 to 16 mm. in their vertical diameters. Circular "pasters" usually measure 17 mm. in diameter. These "pasters" are placed so that they reach the lower edge of the distance lens. The horizontal extent of the field for reading that these "pasters" give is approximately 35 cm. (15 in.)—much too large. They cut off too much of the field of vision for distance in its lower part. If a smaller oval "paster" can be put on the distance lens so that it will give sufficient field area at the reading distance and will also permit of distance vision almost if not quite entirely around it, we shall then have a bifocal lens which will give maximum service with minimum discomfort. After some trials with various lenses and some experiments with various devices the writer has concluded that this can be obtained by the use of a "paster" of oval shape which measures 10 mm. in its vertical and 15 mm. in its horizontal diameter; this gives a field at the reading distance of approximately 19 cm. (7 in.) in the horizontal, and 12.5 cm. (5 in.) in the vertical meridian. If the oval disc ("paster") is placed 2 mm. above the lower edge of the distance lens it will permit of clear distance vision below, sufficient to enable the wearer to see the curb, descend stairs, etc., without trouble; in fact, to be free from the great annoyance occasioned by the ordinary bifocal glasses. It is sufficient to place the optical centers of the portion of the lens for reading at the center of the "paster". The dispersion rays of light occasioned by the edge of the "paster" can be minimized by making the edge very thin. The writer has worn such glasses and finds them excellent for all purposes. In his operative work they are particularly serviceable. Patients also express themselves as being particularly pleased with this form of bifocal glasses.

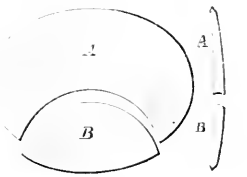

Fig. 3.—"Perfection" Lens.

Fig. 4.—Desirable Form of Lens.

The Reduction of Turbinal Hypertrophies.—D. J. Gibb Wishart believes that this condition is a complex one, dependent not alone on local catarrhal factors, but on environment, climatic conditions, occupation, nervous mechanism, habits of life, and the abuse of tobacco and alcohol. Many of the plans of treatment proposed are unsatisfactory, for the results thereby attained lack the feature of permanency. Permanent relief can be expected only when there is a removal of bone or cartilage. He does not, however, believe in the wholesale removal of tissue. Every possible amount of nasal mucous membrane must be preserved. He, therefore, recommends sub-mucous galvano puncture, or the use of the turbinal trochar or the angular-handled Graefe knife introduced through a linear puncture. The use of the spokeshave in the nose is inadmissible, for the scissors or snare can remove any necessary amount of offending tissue.—*Canadian Practitioner.*

Rabies in Germany.—The Berlin correspondent of the *Lancet* writes that in Germany during the year 1900 there were 230 persons bitten by animals suffering, or suspected to be suffering, from rabies. This number showed a considerable decrease as compared with 1899, when 303 persons were bitten. Of the above 230 persons 187 were treated in the institute for Infectious Diseases in Berlin by injections of Pasteur's anti-rabic serum; the remainder were either treated at home by cauterization or other methods, or did not receive any medical treatment at all. It is remarkable that rabies did not develop in any instance either among the patients who received the injections or among others, so that no case of rabies in the human subject occurred in Germany in 1900. The bites were inflicted by one hundred and sixty-two dogs, five cats, and three cattle. Post-mortem examination showed the existence of rabies in one hundred and two dogs, two cats, and three cattle, and of suspected rabies in forty-four dogs and one cat.

Children's Seaside Sanatoria in Germany.—The Berlin correspondent of the *British Medical Journal* says that the "Society for Children's Sanatoria" at German seaside places can look back on its last year's work with satisfaction; 1,751 children in all (618 of whom came from Berlin) were treated in the four sanatoria of the society, the length of their stay averaging six weeks, but varying, of course, according to circumstances. The total number of days, counting all the four establishments, was 77,222; 14,633 warm baths and 15,184 cold baths were given; 830 of the little patients were dismissed cured, and 765 much improved.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, August 24, 1901.

THE TREATMENT OF CYSTITIS.

THE management of a patient with acute inflammation of the bladder is usually simple enough, and in uncomplicated cases recovery is prompt; but when the disease becomes chronic, we often have a condition which taxes our patience severely. The treatment of those forms of cystitis which are caused by calculus, gonorrhœa, new growth, or stricture must, of course, depend upon the removal of the cause, since the inflammation is distinctly secondary to such conditions, but these conditions are not responsible for the very large proportion of cases of cystitis in which the disease is of a tuberculous nature, and it is tuberculous cystitis which requires such long and patient treatment, both of local and general conditions, and which is so difficult to deal with satisfactorily by surgical means. Von Hofmann has recently (*Die moderne Therapie der Cystitis*, 1901) contributed an interesting monograph on this subject, and he devotes much space to the treatment of tuberculous cystitis, which he considers the most important form of the disease. His main idea is that the disease should be considered general as well as local, and that very active systemic treatment should be instituted. In this regard creosote and guaiacol and their preparations seem to be the best drugs, but the question of nutrition is also of great importance, just as it is in pulmonary tuberculosis. Surgery has been called upon in many cases of tuberculous cystitis, but the most that can usually be done is to establish drainage, unless we should be so fortunate as to meet a case with a circumscribed ulcerative process, which could be treated by scraping or cauterization.

As is well known, the establishment of permanent drainage is, as a rule, followed by amelioration in the patient's condition, since, by it, the bladder is placed completely at rest; but when we want the fistula to close it will not always do so, and the results are very uncertain as to permanent benefit, no matter what treatment is employed in addition to the drainage. Von Hofmann recommends as useful preparations several salts of guaiacol, and specially notices the cinnamylate, and he also insists upon the importance of pushing the patient's nutrition as much as possible.

The local applications which will do good in cases of tuberculous cystitis are various solutions having germicidal qualities, and among other preparations may be mentioned several salts of silver and mercury. Patients will be found to differ in their tolerance of these preparations, and trial alone will show which is best and what strength individual cases will require. The most important reason for failure in treating this unpleasant disease is that the tuberculous process is rarely limited to the bladder, but commonly involves other parts of the genital tract, from which it is difficult or impossible to eradicate it. Our treatment of tuberculous cystitis must, therefore, remain much as it has been, systemic and local; the former consisting in pushing nutrition as much as possible and using some of the drugs which have been mentioned, and the latter consisting in the employment of those operative means which place the bladder at rest or eradicate any accessible foci of disease, and the use of appropriate local treatment by means of germicides and antiseptics. Many patients will improve under such a regimen, but the condition is one of the most unsatisfactory with which the surgeon is called upon to deal. We might add that von Hofmann looks upon the development of cystitis in a patient with an enlarged prostate as a serious matter to be avoided by rigid observance of catheter precautions. If cystitis does occur in such cases, he relies on nitrate-of-silver irrigation, and the internal administration of a urinary antiseptic. Good results in genito-urinary surgery sometimes follow the substitution of an organic compound of silver for the nitrate.

SUBSTITUTION IN MEDICINES.

IN a recent case of death from poisoning, the druggist who gave the wrong medicine offered as an excuse that he had merely substituted one article for another on the supposition that it was of equal strength and much cheaper. The prescriber, in testifying on the trial, stated that the practice was a very dangerous and very frequent one, and was apparently past remedy. While the latter may, or may not, be the case, it is quite certain that with many who claim to be reputable and competent pharmacists the practice of substitution is very common. The number of protests made from time to time in medical journals have reference to only a very small percentage of offenders, inasmuch as the larger number of such do not happen to be discovered.

The question of prevention, however, is a very serious one from every point of view. The physician, in his direct and responsible connection with the trustful patient is the one most concerned, although drug manufacturers also have a right to claim fair play regarding the guaranteed qualities of their products. With both parties it should be the real thing or nothing.

From the business point of view it is a fraud on the producer and, from the ethical view, a danger to the consumer. Both parties in the compact have thus a common cause against the middle-man who surreptitiously plays the part of thimble-rigger and steerer.

The temptation to substitution is always strongest with the most expensive medicaments, and in the case of such as have a known quality of efficacy. An inferior and oftentimes inert article is almost invariably used when substitution is practised. Thus the manufacturer and the prescriber are always placed

in a false light with the patient, who expects certain promised results.

Generally speaking, the physician is the one to suffer the most, as his disappointed client is apt to leave him for another. How many lost patients can be accounted for in this way it would be difficult to imagine. The too trustful physician is in a very bad way between the prescribing druggist on the one hand and the ever-ready substituter on the other. Must he be compelled to turn dispenser himself in sheer defence? Certainly, in some cases, the crime has, in this way, met its penalty. But when we look about for a remedy against the evil we butt against the bulwark of general depravity and the impossibility of applying ordinary missionary efforts. The only thing is to discover and then to punish. The man who substitutes once will do so again. He has no conscience to begin with and nothing, in fact, to which an appeal can be made. The whole question then narrows itself down to that of mutual trust and the dispensing of original unbroken packages.

THE FUNCTION OF MINUTE RESEARCH IN BIOLOGY AND MEDICINE.

To the great majority of the profession, especially to the "busy practitioner," the laborious researches of the biologist, the pathologist, and the chemist do not always appear to have a bearing upon actual practice. It was probably to counteract this tendency that the authorities of the Yale Medical School, at the annual commencement in June, invited Dr. Edmund B. Wilson to deliver the annual address to the graduating class on "The Higher Claims of Minute Research in Biology and Medicine" (*Yale Medical Journal*, July, 1901).

Ever since the announcement of Schwann's cellular theory of life, and Virchow's cellular theory of morbid processes, the point of view of the pathologist and the biologist has been the same. Both are now workers in the same field, who view vital phenomena in the focus fixed for them by the two men named, as well as by Darwin, Huxley, and Spencer. Both realize, to-day, that in the study of the origin and evolution of the subtle vital processes which go on in the cell lies the key to the problems of life and disease.

In order to illustrate the practical application of minute research in biology and medicine, Dr. Wilson, in his address, chose two problems which these sciences have been trying to solve—heredity and the origin of tumors—and gave his hearers a glimpse of what has been done in this field, together with a prophetic vision of what may be expected as the result of these investigations. In what follows we have endeavored to give a brief summary of the theme as gleaned from Dr. Wilson's address.

In studying the phenomena of cell-division it has been found that "the fertilized egg receives the nuclear material in exactly equal quantity from both the parents, in the form of rod-like bodies, known as chromosomes, that are identical in number, form, and size in both male and female. Our researches on cell-division are converging with ever-increasing probability to the conclusion that the paternal and maternal materials contained in the chromosomes are, or at least may be, equally distributed by division to all the cells of the body, whatever be their structures or functions. In other words, every cell may thus receive nuclear material from both parents, and thus bear within itself the germs of the hereditary predisposition of both." Further studies are necessary in order to establish this conclusion completely. When this has been done, we may understand how mental and physical characteristics have been handed down from parent to offspring on both sides from generation to generation.

As regards the origin of tumors, Dr. Wilson quotes Prudden, who, in a recent article (MEDICAL RECORD, March 10, 1901), has told us that in the study of the cell itself lies the elusive answer to this question. Experimental studies with cells under artifical conditions have shown how unfavorable influences may sway the process of growth and differentiation, and it has even been found that the unfertilized egg may be goaded to complete embryological development by chemical stimuli. Again, under certain chemical conditions, the egg, "as it were, loses control of itself, and gives way to a course of riotous living, producing, not a normal embryo, but strange and monstrous forms." Here we seem to be hot on the trail of the cause of tumors.

THE MURMUR OF MITRAL STENOSIS.

THERE are few phenomena in physical diagnosis that have been the source of so much discussion and difference of opinion as the murmur of mitral stenosis. The explanation for this fact probably resides in the circumstance that variations in the character and degree of the lesion, together with other concomitant conditions, give rise to corresponding variations in the resulting objective physical signs. Mitral stenosis is in general attended with a sensation of thrill or purring tremor over the body of the heart, apparently coinciding with the period of auricular systole; and with a peculiar, characteristic, rumbling murmur—that once heard is likely ever afterward to be recognized—either continuing into the systolic murmur of associated mitral regurgitation or being followed by a short, sharp, vigorous muscular first sound, the second sound being largely lost in the quickly recurring presystolic murmur.

While it is the almost universally accepted opinion that the murmur of mitral stenosis is presystolic in time, there are some who hold a dissenting view, maintaining that it begins with the movement of the ventricular systole. For the purpose of reaching a definite conclusion in the matter Dr. Hugh Walsham (*Lancet*, May 18, 1901) has studied systematically with the aid of the Roentgen rays a series of cases of mitral stenosis. He found, first of all, that in the normal heart the movement of the apex is heaving, being attended with somewhat rapid displacement toward the left and followed by a more rapid retreat toward the middle line. The greatest displacement, however, does not involve the apex, but rather the middle of the left border, corresponding to the ventricular cavity at a point where it is crossed by the left fourth rib. On auscultation the first sound of the heart is found to occur synchronously with the retreat of the cardiac shadow toward the middle line—corresponding to the ventricular systole, immediately after its projection toward the left—corresponding to the auricular systole. In the interval corresponding to the period of repose—

slow and progressive distention of the shadow of the ventricular wall is occasionally seen. The visible and palpable cardiac impulse coincides with the auricular systole, while the succeeding shock is due to the ventricular systole. In fact, the position of the shadow that corresponds with the cardiac apex is in some cases below the point of cardiac impulse against the chest-wall.

Now, in cases of mitral stenosis it is found that the thrill conveyed to the palpating finger, as well as the murmur heard on auscultation at the point of maximum intensity, corresponds to the advance of the left border of the heart toward the left and ends abruptly with the retreat of the border toward the middle line—therefore coinciding with the auricular systole.

These interesting observations would seem to establish beyond doubt that the murmur of mitral obstruction and the accompanying thrill are presystolic in time. As is quite well appreciated, there is also often some degree of mitral insufficiency, so that the presystolic murmur is frequently continued directly into a systolic murmur.

News of the Week.

Koch's Modified Statement.—Professor Koch has issued a statement amending in two important particulars the address delivered by him before the Tuberculosis Congress in London. In commenting on his address, the MEDICAL RECORD said that his experiments were practically the same as those of Theobald Smith, although the mention of the latter by the orator was such as to give the impression that Smith had followed and not preceded Koch. He now says, in answer to this criticism, that he laid no claim either to priority or monopoly to any ideas propounded in the address, but "I sought only to tell of my own private experiments, and was, in fact, glad of the opportunity given to mention my contemporaries in some of their experiments, among whom was one of America's greatest medical authorities, Dr. Theobald Smith." Regarding the danger of infection from tuberculous cattle, he said, in the address: "I should estimate the extent of infection by the milk and flesh of tuberculous cattle and the butter made of their milk as hardly greater than that of hereditary transmission, and I therefore do not deem it advisable to take any measures against it." As modifying this uncompromising statement, he now says: "I did not mean to recommend the abandonment of comprehensive and expensive systems of regulation, prevention, and inspection that are now in operation. I simply said that it was injurious and unnecessary to go further with such systems when we were justified in expecting that our long-sought remedy was found and almost within our reach. Why, then, should we rear higher structures which must inevitably fall to the ground?" He very justly adds that experiment and not argument must now be the watchword of medical and scientific men who would conquer tuberculosis.

The Death of Dr. Moncorvo of Rio de Janeiro is announced. He was well known as an original worker in pediatrics, and the therapeutics of this important branch of medicine has been greatly enriched by his labors.

An Egyptian Medical Congress will be held at Cairo, December 10-14, 1902, under the patronage of the Khedive. The work of the congress will be especially devoted to the diseases peculiar to that country, such as ophthalmia, bilious remittent fever, abscess of the liver, ankylostomiasis, bilharzia, etc. An invitation has been extended to foreign medical men to participate in the discussions and read papers on appropriate subjects. The secretary-general of the congress is Dr. Voronoff of Cairo.

The American Veterinary Medical Association will hold its thirty-eighth annual convention at Atlantic City, September 3d to 6th. The topics to be discussed will be the communicability of tuberculosis from animals to man, the malaria-transmitting capacity of the mosquito, and new methods of meat and milk inspection. The society will also hear the report of the committee on the formation of a regular veterinary surgeons' corps in the United States Army.

A Memorial to Dr. Lazear.—A committee consisting of Drs. William Osler, Stewart Paton, and William S. Thayer was appointed some months ago, at a meeting of the friends of the late Dr. Jesse William Lazear, to receive subscriptions for a memorial to him and his work. Dr. Lazear was born in Baltimore county, Maryland, in 1866, and graduated from the academic department of the Johns Hopkins University in 1889. In 1892, he received the degree of M.D. from Columbia University in this city. From 1892 to 1895, he spent his time in study and investigation in Europe and as an interne at the Johns Hopkins Hospital in Baltimore. During the following three years and a half, while a member of the staff of the Out-Patient Department of the Johns Hopkins Hospital, he did much valuable work as a teacher and investigator in the laboratory of clinical pathology. In February, 1900, he became an acting-assistant surgeon in the army and was assigned to duty in Havana, where he was appointed a member of the army commission for the study of yellow fever. The final proof of the discovery that the disease is transferred by the bite of a certain mosquito could be obtained only by direct experiment upon a human being. To this experiment Drs. Lazear and Carroll courageously subjected themselves, and in the performance of this heroic duty the former lost his life.

Epizootic in Philadelphia.—A severe epidemic of influenza is prevailing among the horses in the suburbs of Philadelphia. In Radnor, Bryn Mawr, Ardmore, Overbrook, and all of the suburbs to the west of Philadelphia the disease has attacked great numbers of horses, draught animals and those in private stables suffering equally.

War Against Mosquitos in New Orleans.—The Board of Health of New Orleans has entered upon a war of extermination against mosquitos in two of the wards of the city. The district was assigned to our sanitary inspectors, who have devoted their entire attention to it during the past week, visiting every one of the 5,000 premises in the district, inspecting all water supplies and treating all possible places for the incubation of mosquitos with oil. It was decided to use paraffin oil in the cisterns, the chemist of the board having recommended that as the most successful in destroying mosquitos. Crude Beaumont oil will be used in the gutters and open ponds. Dr. P. E. Archinard of the Board of Health is superintending the work. The householders have been requested to renew the oil treatment weekly, the oil being supplied by the Board of Health.

Management of the State Hospitals.—Governor Odell made last month a visit of inspection to each of the State hospitals for the insane, and it is reported that the result has been a decision that the

State is paying a very high price for the services that it is receiving and that the cost of maintenance of the hospitals is extravagant. The Governor will, it is said, make a recommendation to the next legislature that the salaries of many of the officers of the hospitals be materially reduced and that a new system regarding supplies be adopted whereby a saving can be made in their cost.

Typhoid Fever in Chicago.—The Nineteenth Ward Improvement Association of Chicago held a mass meeting at Hull House one evening last week to discuss ways and means of putting an end to the prevalence of typhoid fever and malaria in that part of the city. Visiting nurses from Hull House are taking care of more than thirty patients, and in nearly every block there are from one to five persons stricken with fever. The meeting made an appeal to the City Health Department for help, and also issued a bulletin on the unsanitary conditions which are allowed to prevail in the district.

Zoological Nomenclature.—One of the chief points of discussion at the International Zoological Congress, held last week in Berlin, was that regarding nomenclature. The American delegates favored the adoption of a simple system and the substitution of abbreviated terms; the French proposed to make the existing nomenclature conform more strictly to the classical forms, grammatically and etymologically; the German delegation submitted a compromise proposition. The French proposition was finally adopted.

An Abortive Test of Bellinzaghi's Yellow-Fever Serum.—An order was issued recently by the U. S. War Department, convening at Havana a board of medical officers under Major Havard, Chief Surgeon of the Department of Cuba, for the purpose of supervising the experiments of Drs. Caldas and Bellinzaghi with their alleged yellow-fever curative and prophylactic serum. This order is said to have been issued at the request of the Brazilian minister at Washington, Dr. Caldas being of that nation. The experiments did not go very far, however; for two of the men bitten by infected mosquitos died. They were Spaniards and offered themselves to the Yellow Fever Board as subjects for experiment, as they wanted to become immune. They were healthy before the mosquitos bit them, but developed the fever four days afterward. Dr. Havard says that this will stop further experiments in which mosquitos are used, as they are more dangerous than was expected. Others who were bitten have developed the disease in a light form. The report does not state whether the serum was used in these cases either as a prophylactic or as a curative agent, but if it was it failed most signally. It was rather curious that the experimenters should have left Rio de Janeiro, where plenty of material is presumably at hand, to work in Havana, where material has become so scarce that it must be created by mosquito inoculation. Dr. Caldas claims to have discovered the true yellow-fever germ, but keeps his discovery a secret.

Suit against Physicians in Indianapolis.—A man who was sent to the Central Hospital for the Insane in Indiana as insane and afterward released has filed suit for $15,000 damages, making defendants the justice who committed him and the constable who took him to the hospital, together with doctors and other employees of the city dispensary. He charged that on or before June 24, 1901, the defendants entered into a conspiracy, as an insanity commission, to hold insanity inquests and divide the fees. This is a result of recent charges regarding what the local papers called the "insanity trust," it being alleged that a number of physicians and others had conspired to commit persons to the asylum without legal forms, in order to secure the fees for examination.

Dr. Thomas D. Wood has resigned as professor of hygiene and organic training at Stanford University, California, and accepted a similar position in the Teachers' College of Columbia University in this city.

A Diploma Mill in Jersey City.—The New Jersey State authorities, at the instance of Dr. J. M. Mitchell of Red Bank, Secretary of the State Board of Health, have closed the "Central University of Medicine and Science" which claimed to be incorporated under the laws of New Jersey, and which conferred diplomas on anyone who thought them worth ten dollars apiece, or two for fifteen dollars, and had the money to back up his convictions. The degrees conferred were denominated "honorary," and so, the circular of the concern announced, could be had without any examination. Although the degrees most in request, apparently, were those of M.D. and Ph.D., any others that might be called for could be supplied at the regular rates. The "university" seems to have been doing business for only a short time, and probably has not had many "graduates" yet.

The Medical Society of the Borough of the Bronx will hold its first regular meeting of the autumn at the Metropolis Theatre Building on Wednesday, September 11th, at 8 P.M. The secretary is Dr. Albert C. Geyser.

Operations at the Cook County Hospital.—The authorities of this hospital in Chicago recently posted a notice to the effect that all major operations must be performed by one of the attending staff only, the work of the internes being restricted to minor surgical cases. The house staff resented this imputation of incapacity, and has made a public protest. In this it is asserted that every one of the internes had had a college training before beginning the study of medicine, had been graduated from a reputable medical school, had passed the State board examination, and been licensed to practise medicine and surgery in Illinois, and finally had obtained his hospital appointment after a rigid competitive examination. In reply to the charge that there had been too much and unnecessary operating by internes, they state that no operation has ever been performed until after a thorough examination by a member of the attending staff, and except under his immediate supervision. "Considering the qualifications necessary to become an interne," they say, "and the fact that every senior interne has served twelve months in preparing for surgical work, it is justly evident that we should be regarded competent to participate adequately in the care of patients. Such privileges are enjoyed by internes of every other hospital in this country and abroad."

Leprosy in a West Virginia Mining Camp.—The West Virginia State Board of Health has been informed that leprosy exists among the foreigners in the mining districts in the eastern part of the State. An investigation will be undertaken to determine the truth of this report.

The Illinois Board of Dental Examiners.—Governor Yates of Illinois, a few days ago, requested the resignation of the State Board of Dental Examiners, and has appointed a new board in its place. This action was taken on information furnished by

the United States Consul at Munich, Germany, who is said to have in his possession diplomas which had been issued improperly. An explanation has been made by the president of the board, from which it would appear that the licenses were given according to a negligent system, by which the name of the recipient of the license was filled in after the signatures of the members of the board had been attached. A former member of the board has been arrested on three warrants, one for forgery in issuing licenses, a second for malfeasance in office, and a third for accepting a bribe, it being charged that he issued a license to a man who was not a graduate of any college, on the payment of $400. It is stated, however, that this system of signing blank licenses was discontinued some time ago. The secretary of the board, Dr. J. G. Reid, who was instrumental in securing evidence against the accused member, has been reappointed by the Governor on the new board.

Threatened Famine in Russia.—The annual struggle of the Russian agriculturist to snatch from the earth during the brief growing season enough food to supply his wants during the long winter has in great measure failed again this year. The cause for the failure this year is the same that reduced the yield of cereals in our own land, intense heat and drought, followed by torrential rains. According to the official report, only two provinces out of seventy have had good harvests, the rest running from below average to utter failure. There has been a very large yield in Siberia, but a distribution of food stuffs to those in the famine districts is impossible because of the few railways and the almost entire lack of passable roads. With the famine, which seems inevitable, will doubtless come the usual epidemics of relapsing and typhus fever.

Obituary Notes.—Dr. James A. Williams of this city died on Thursday at Armonk, Westchester County, where he had gone with his family with the hope of improving his condition. Dr. Williams was born in Sinking Springs, Ohio, sixty-one years ago. He was graduated from the Rush Medical College, Chicago, in 1861, and from Bellevue two years later. He entered the army as a surgeon, and was soon advanced to the rank of major, being the youngest in the army to hold that title. After the war he practised for a short time in Mattoon, Ill. From there he came to New York, where he remained in active practice up to within a couple of months of the time of his death.

Dr. James M. Howard, Jr., of Masontown, Pa., was killed in a runaway accident at Fairmount, W.Va., on August 10th. He was twenty-three years of age, and a graduate of the Jefferson Medical College, Philadelphia. He was the son of a physician.

Dr. Benjamin H. Kittrell of Winona, Miss., died recently at Fourth Lake. He was a graduate of the Medical Department of Tulane University, New Orleans, in the class of 1897. He was an acting assistant surgeon in the Spanish war, and was in the hospital at San Juan Hill during the Santiago campaign.

Dr. David Cory of this city died on August 19th. He was a graduate of the Medical Department of Columbia University in 1866.

Dr. John Duncan of Victoria, B. C., was drowned in the sinking of the *Islander* off Douglas Island, Alaska, on August 15. He was a graduate of the Medical Department of McGill University, Montreal, in the class of 1884.

Book Reviews.

Public Water-Supplies. Requirements, Resources, and the Construction of Works. By F. E. Turneaure, C.E., Professor of Bridge and Sanitary Engineering, University of Wisconsin, and H. L. Russell, Ph.D., Professor of Bacteriology. With a Chapter on Pumping Machinery by D. W. Mead, C.E., M.Am.Soc.C.E., etc. New York: John Wiley & Sons; and London: Chapman & Hall, 1901.

This work, although prepared for teachers and students of technical schools, contains very much that will interest physicians. Prefaced with an admirable historical sketch of ancient methods and works from Joseph's well at Cairo to Roman aqueducts, it contains valuable chapters on the quantity and quality of water, source and examination of water-supplies, collection works, and methods of purification. The chapters on ground-water and the quality of water are especially concise, plain, and practical. The popular belief that aeration greatly improves a water is erroneous according to the authors. This assertion, however, is modified in the case of stagnant ponds and reservoirs in which putrefactive changes have taken place. Though aeration may not—actually does not, according to experiment—help Niagara water, it does help to purify the water of a filthy duck-pond.

The conclusion of the authors that a stream, once sewage polluted, should never be used for drinking water as long as there is any evidence of pollution present, is thoroughly sound and modern doctrine. The self-purification of streams, of which we used to hear so much, is an indefinite and unknown factor.

The information contained in the chapter devoted to water-borne diseases should become public property. Bacterial examination of water is treated at the length it deserves, and due credit is given the colon bacillus as an index of sewage pollution.

The prevention of the waste of water is an ever-present topic to us in America, where in some cities the consumption of water is easily double the amount that could possibly be used legitimately. When one considers that all this waste means increased municipal expense and consequent increased taxation, the importance of this subject cannot be overestimated. Several pages are devoted to this question, and the authors recommend the meter as the easiest and most rational method of preventing waste.

The second part of the work contains chapters on the construction of water works, valuable to the engineer and the sanitarian—and to the taxpayer also, for some space is deservedly devoted to the cost of erection and yearly maintenance of these works. The various forms and methods of collection, both of surface- and ground-waters, are treated of at length.

The purification of water is given an appropriate amount of space, prominent in which is the method of natural sand filtration. The value of this method, which has improved so much with our increase in bacteriological knowledge, is apparent in the reduction in typhoid death-rates after its use—amounting in some instances almost to ninety per cent. Information regarding covered sand-filters, their method of construction, cleaning, and cost, is given in detail.

The authors have very little to say in favor of the various household filters. Boiling is the one safe and efficient method for domestic purification.

On the whole this work is to be recommended to any one who has to do with any phase of the water-supply question. Its completeness and thoroughness are commendable features.

Operative Surgery. By Joseph D. Bryant, M.D., Professor of the Principles and Practice of Surgery, University and Bellevue Medical College, Visiting Surgeon to Bellevue and St. Vincent's Hospital, etc., etc. Vol. II. Operations on the Mouth, Nose, and Œsophagus, the Viscera Connected with the Peritoneum, the Thorax and Neck, Scrotum, Penis, and Miscellaneous Operations. Eight hundred and twenty-seven illustrations. New York: D. Appleton & Co., 1901.

The publication of this volume, somewhat delayed apparently, completes one of the best works on operative surgery in existence, and we therefore greet it with pleasure. The title recites the contents of the volume, in which we find much of what is most important in surgery.

The pictures are graphic and handsomely executed, and the plan of giving illustrations of the instruments required in particular operations is maintained. The author's literary style is so good that much is added thereby to the pleasure of reading the book. The volume begins with a consideration of the operations upon the nose, mouth, and œsophagus, which are included in one chapter, after which the surgery of the

abdomen is taken up and naturally occupies most of the book. The various forms of intestinal suture are explained largely by diagrams and illustrations, and the newest methods of closure with instrumental assistance receive attention. Certain abdominal operations cannot be well shown in an illustration, though a diagram is often valuable, and in this regard some illustrations in this work fail to show clearly what is intended. However, almost all attempts to make a useful picture of such an operation as gastro-enterostomy are failures. The various operations on the ureters receive considerable space, and the suture methods are carefully described. A few pages are devoted to the methods of examination of these canals, with descriptions of the necessary instruments. The important subject of hernia is perhaps the best illustrated of any in the book. All the modern methods of operative treatment are described and illustrated. The description of the radical operations for malignant disease of the rectum is very complete, and forms a valuable chapter of reference as well as an operative guide. The various methods of removal of the mammary gland and its related lymphatics receive the attention which so important a subject deserves. The author is an advocate of the advanced radical treatment whenever possible. The remarks on the operative surgery of the lung lead us to hope that there is a future of increasing brightness in this branch of surgery. Vesical surgery and its extensive armamentarium are well illustrated and described. Some of the most recently suggested methods in bone surgery are mentioned under the head of miscellaneous operations, as is also the operation for removal of the cervical sympathetic.

This volume completes a work which is a credit to American surgical literature.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Vol. XII., 1900. Edited by WALTER LESTER CARR, M.D., of New York.

This book, which is reprinted from the *Archives of Pediatrics*, contains twenty-three articles dealing with a great variety of subjects connected with the diseases of childhood. They show the scope of this specialty and the character of the scientific work done by this society.

SAUNDERS' MEDICAL HAND-ATLASES. I. ATLAS OF LABOR AND OPERATIVE OBSTETRICS, fifth edition. II. ATLAS OF OBSTETRIC DIAGNOSIS AND TREATMENT, second edition. By O. SCHAEFFER, Privatdocent in Obstetrics and Gynecology in the University of Heidelberg. Edited by J. CLIFTON EDGAR, A.M., M.D., of New York. Philadelphia and London: W. B. Saunders & Co. 1901.

Both of these atlases are translations of the Lehmann-Medicinische Handatlanten, and are remarkable for their artistic excellence and scientific accuracy. Another distinguishing feature which must appeal to the practitioner who is in quest of information and not of attractive specimens of the bookmaker's art is that the numerous illustrations in these atlases are not inserted because they are pretty and help to fill up, but because they actually present in a clear and striking way some obstetric truth. The text is also of an able part well.

The first volume is divided into two parts, the first of which the act of parturition is considered from the standpoint of the practical obstetrician, and the second deals with obstetric operations.

The second volume might very properly be called a textbook on obstetrics, for even to a greater degree than the first volume it may be said to be complete, and, nevertheless the best results will be obtained by using it in connection with a larger treatise on obstetrics. In this edition many new plates have been added, and the text has been carefully revised, rendering it more available for quick reference by the student. The type for the practical or clinical portions of the work treating more especially of the science of obstetrics. The symptomatology and treatment receive more detailed consideration in this edition.

CLINICAL LECTURES ON SURGERY OF THE KIDNEY AND ENLARGEMENT OF THE PROSTATE. By P. J. FREYER, M.A., M.D., M.Ch., Surgeon to St. Peter's Hospital. Lieutenant-Colonel Indian Medical Staff (retd.). New York: William Wood & Co. 1901.

This little work presents in a concise and practical way the methods of dealing with the affections mentioned in the title.

The lectures are reproduced from published clinical reports in the *Lancet* and *Clinical Journal*, and represent the author's personal experience as expressed in lectures at the Medical Graduates' College and Polyclinic. There are only 115 pages, but the ground is well covered, and there are illustrations of instruments and diagrams of the various operations which the author considers the most advantageous.

Correspondence.

LETTER FROM JAPAN.

(From Our Special Correspondent.)

RECEPTION TO DR. S. WEIR MITCHELL—JAPANESE STUDENTS ABROAD—THE HEALTH OF THE NAVY—A JAPANESE VARIANT OF CHRISTIAN-SCIENCE FOLLY.

TOKIO, July 5, 1901.

THE visit of Dr. S. Weir Mitchell has created a very good feeling among the Japanese medical men, who joined together in giving himself and party a warm welcome in the shape of a Japanese entertainment at the Maple Club in Tokio. The speeches on the occasion by such men as the President of the Medical Department of the University of Tokio, Dr. Kitasato, the noted bacteriologist and Director of the Institution for the Investigation of Infectious Diseases; Dr. Miura, Professor of Nervous Diseases in the University; Baron Saneyoshi, F.R.C.S., Chief of the Navy Medical Department, and Dr. Takaki, Dr. Saneyoshi's predecessor, now Director of the Charity and Tokio Hospitals, all indicated an increasing friendship for America, and a deep desire to cultivate the acquaintance of their colleagues in our land. The labors of Americans in the various fields of investigation, and the practical results therefrom are evidently becoming more and more appreciated by the Japanese, who, having been educated under the direction of German professors, have hitherto looked to Germany for everything medical.

The present seems a very suitable opportunity for improving this relationship by the establishment of a few free medical scholarships for Japanese in some of the principal universities in America. In the departments of law, literature, and other sciences many Japanese have been graduated, having been attracted to our universities by their manifestly great advantages, but in medicine alone comparatively few Japanese have sought instruction in our universities and colleges.

As English is now being taught in all the principal schools in the Empire, the class of students from which suitable candidates can be drawn is quite large compared with that which furnishes students who desire to study in Germany. The writer of this article once induced the authorities of his *Alma Mater*, the University of Pennsylvania, to establish a scholarship for Japanese students, but the value of the scholarship included only an abatement of the fees, and made no provision for other expenses. Only a few applied, as the cost of the return journey and maintenance during the university course was much beyond the means of any but the wealthiest Japanese students. The following is the number of government students now studying abroad (of which a fair proportion are medical students) and the schools from which they went in Japan: Education Department, 3; Tokio Imperial University, 32; Kioto Imperial University, 22; Higher Commercial School, 2; Higher Normal School, 22; the first to the fifth Higher Schools, 8; Tokio Industrial School, 8; Osaka Industrial School, 2; Tokio Fine Arts School, 4; Tokio Musical Academy, 2; Foreign Language School, 2; Sapporo Agricultural School, 3; Kyoto Higher Normal School, 2; Independent, 8. Total, 120.

At the above-mentioned entertainment Dr. Stuart Eldridge spoke in behalf of the foreign medical men, of whom Dr. W. S. Wells, Dr. Teusler, Dr. C. H. H. Hall, Dr. F. E. Harris, U.S.N., and Dr. W. N. Whitney were Americans practising in Kobe or Yokohama.

It is understood that Dr. W. W. Keen of Philadelphia will shortly visit Japan, and also Dr. de Schweinitz of Philadelphia, both of whom will receive a warm welcome, as did Dr. H. C. Wood, who favored us with a visit last year.

Among the statistical publications that of the Japanese Navy furnishes interesting material for consideration. According to the last Annual Report of the Surgeon-General of the Navy the mean daily force in the service during the year 1898, exclusive of commissioned officers, was 18,420. The total number of cases of disease and injury was 22,222, being a ratio of 1,193 per 1,000 men, an increase of 88 per 1,000 compared with the record for 1897, and 243 per 1,000 compared with the average figure for the past 14 years. This record looks startling, but the explanation is that in 1898 a new system of writing up the sick list was adopted, slight cases being entered which had been previously omitted. If we turn to the number of deaths the indications are quite different, for these are entered at 0.34 for the year, being 0.34 per 1,000 patients, or a decrease of 2.93 per thousand compared with 1897, and a decrease of 0.01 per 1,000 compared with the average of the preceding 14 years. There were 7 deaths from injury and 25 from disease.

Further reading [illegible] as elsewhere, but if one

may judge from recent investigations by Rev. Arthur Lloyd of Tokio, a certain very popular sect, called the *Remmon Kyōkwai* or Lily Gate sect, is not unlike Christian Science in several respects. This sect was founded by a certain Yanagita, but owes its popularity to a woman, Shimamura Mitsuko, born in 1831 in the village of Yoshika. When she had reached the age of fourteen, the son of a fisherman living in an adjoining village was adopted as her husband. After a few years her husband was retransferred to his own family, that he might become the successor of his father. This, of course, involved his divorce from Mitsuko, which seems to have been acquiesced in because it opened a path out into the world. Some of the opponents of the Remmon Kyōkwai say that she went about this time to Shimonoseki and led an unsavory life there in connection with a company of rice speculators, to whom she acted the part of a clairvoyant. Afterward she drifted across the straits and became an inmate of a *samurai* family of Kokura, Kyushu, until, through the mediation of the head of this family, she became the wife of one Shimamura Otokichi, a dealer in rice, who had won the favor of Lord Ogasawara of the Kokura clan. Unhappily in 1852 Mitsuko became sadly rheumatic, an almost helpless cripple in fact. At this juncture she applied to Yanagita, who had gained quite a reputation for his skill in treating similar disorders. At the first interview the shrunken cords of her neck and limbs were relaxed. This evidence of her sturdy faith seems to have convinced Yanagita that she was worthy to be the herald of the new faith. In the work of propagation she made large use of gatherings of the young of both sexes, and thus incurred the suspicion of the authorities. This sect had its source in the Nichiren sect of Buddhism, and Mitsuko in one of her addresses asserted that she was the reincarnation of Nichiren himself. The special claim made by the preachers of the sect is that diseases, whatever their nature, are healed summarily in response to prayer. On the ethical side, the teaching of the sect is essentially the popularized Confucianism of the Shingaku and Kyūō Dōwa.

OUR PARIS LETTER.

DEATH DUE TO MEDULLAR COCAINIZATION—SERIOUS ACCIDENTS RESULTING FROM COCAINE ANÆSTHESIA—CASE OF DEATH FROM THE USE OF EUCAIN—POST-GRADUATE COURSE IN PARIS.

PARIS July 27, 1901.

DR. BROCA, surgeon of the Paris hospitals, reported a case of death from medullar cocainization at a recent meeting of the Society of Surgery. The patient had been operated on by Dr. Prouff, who sent the observation to Broca. The patient was a woman sixty-two years old, who imagined she had a foreign body in her foot, and insisted on being operated upon, although the Röntgen rays had given a negative result. Local anæsthesia might have been used, but as there was chronic arthritis of the hip and knee, Dr. Prouff decided to use an intrarachidian injection, so that he might investigate the lesions caused by this affection. One cubic centimeter of Carrion's solution was injected. The anæsthesia was perfect, and the patient was able to get up and walk without difficulty immediately after the operation. There was no vomiting nor headache, and an hour after the injection she went home on foot, a distance of two hundred yards, and walked up several flights of stairs. The same day, in the afternoon, there was a noticeable change, extreme rachialgia being a prominent feature. Dr. Prouff was called, and found the woman very pale, with a weak pulse, and suffering from atrocious pain in the vertebral column. He had her get up and walk, and as there was no motor or sensory change he thought it sufficient to reassure her and to recommend a little patience. Death took place the next day.

Dr. Broca remarked that he, as well as his colleagues, had been asked to report all cases of death taking place after medullar cocainization. It seemed to him that this was a perfectly clear case, and it could be therefore argued that it was best not to recommend the use of this method indiscriminately.

Dr. Nélaton said that he had noticed recently very serious cardiopulmonary troubles after an injection. There were dyspnœa, pallor of the face, and a very weak and frequent pulse. Caffeine was used as a stimulant with favorable results. An analysis of the solution was made, and it was found to contain certain secondary products resulting from the decomposition of the cocaine. Dr. Rochard confirmed what Nélaton had said as to the changes observed in different solutions. A certain product called ecgonine is sometimes found, and the latter seems to have properties akin to those of atropine. Dr. Segourd, the celebrated gynecologist, said that he had tried Tuffier's method four times, and though he had experienced no difficulty in using the technique indicated, he had ceased employing it, as he found that he was disturbed during his operation by the excessive tremor the patients suffered from. Dr. Chaput advocated a second puncture and the removal of twenty cubic centimeters of cephalo-rachidian liquid, thereby preventing the usual accidents, such as vomiting and headache. Dr. Tuffier remarked that the case of death cited by Broca could not be discussed as to its cause, as the autopsy was not made. Moreover, the manner in which the patient was treated was such that it seemed to him that the operator was certainly as much to blame as the method.

At the following meeting held on the 10th of July, Dr. Bousquet reported a case of death after an injection of eucaine. The patient, a woman, was to be operated on for a strangulated crural hernia. Immediately after an injection of two centigrams of eucaine, she grew very pale, the pulse became small, and the breathing labored. Artificial respiration and injections of caffeine and other were tried and the patient improved. Extreme agitation came on, however, and in the evening she was in a comatose condition. She died at two o'clock in the morning.

In an article published recently in the *Presse Médicale*, Dr. Jayle, assistant of Professor Pozzi, advocated the creation of a certain number of post-graduate courses such as those held in Berlin and Vienna. Dr. Jayle said it was a noticeable fact that foreigners were deserting more and more the Paris School of Medicine, and the reason of this was not the lack of clinical instruction that was to be obtained nor the dearth of capable instructors, but rather the fact that there was no organized body of lecturers, which made it difficult for the foreign students to find what they wished, and to acquire in a relatively short space of time the knowledge they needed. There is perhaps no place in the world where a larger variety of skin affections can be studied than at the St. Louis Hospital, the French specialists for gastro-intestinal affections rank among the highest; in children's diseases there are no better men to be found than Comby, Moizard, Hutinel, and Marfan, and yet there is such a lack of initiative and organization that foreign students come here to spend a few weeks, visit a certain number of hospitals, and then go on to Berlin and Vienna. Nothing can be looked for from the Faculty of Medicine, which remains absolutely inert. The municipal council, which has already created two cliniques—those of infantile surgery and of gynecology—will most likely undertake the creation of a municipal institute of applied medicine. One of its members, M. Auffray, has just published a report on the subject, which is given in full by Dr. Jayle, and which conveys a good idea of the crisis which is occurring in medical instruction in France. In this report mention is made of the fact that in former times students of other nations were allowed to come to France, graduate, and practice, whereas the laws are now much more strict, and a thorough knowledge of French is demanded of those who wish to become physicians in France, the two diplomas of bachelor of letters and bachelor of sciences from a French university being required. What is needed, therefore, is not a course of instruction to be given in three or four years, but one that will last only a few months, and that will be of a more practical nature. This course would be open only to physicians already having their diploma, and would correspond to the post-graduate courses in America.

LIME WATER AS A CULICICIDE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: I write to offer what, in my opinion, is a simple, cheap, and sanitary method of ridding tanks and pools of the larvæ of mosquitos and preventing their deposit therein. For a number of years while living in Florida I used water from a small cistern to which mosquitos had access, and as a natural consequence in that region the water in the cistern would in warm weather occasionally contain a large number of wrigglers. When this occurred I would simply put a lump of unslaked lime into the cistern, or some air-slaked lime when I did not have the unslaked, and the larvæ would disappear as if by magic, and the water, which had previously assumed a yellowish tinge, would become as clear as crystal. The water would for awhile taste slightly of lime, but not disagreeably so.

Recently I accidentally discovered a rain-barrel full of water which was alive with the larvæ and pupæ of mosquitos, the former being vastly in the majority, and I immediately seized upon this opportunity to watch the effect of lime upon them. As I was not trying to ascertain the minimum quantity of lime necessary to kill the larvæ, but only to redemonstrate to myself that lime would do the work, I dumped my two hands heaping full of air-slaked lime into the barrel. This was done at 2.30 P. M. On inspection the next day at 7.30 A. M. there was not a single live larva in the barrel, but the

number of pupæ was apparently undiminished. Another inspection at 5 P. M. the same day showed no live pupæ or larvæ, and the water, which before the introduction of the lime was dark and foul, was clear, and dead larvæ were plainly discernible on the bottom.

The smallest amount of lime to a given quantity of water necessary for the purpose could easily be ascertained by experiment. If upon investigation the quantity is found not to be incompatible with health, the judicious use of a little lime would be a great boon to the inhabitants of such a place as New Orleans, where the majority of the families drink rain-water out of mosquito-breeding wooden tanks.

As bearing upon this subject I call attention to the absence or scarcity of mosquitos in typical limestone regions, and incidentally to the fact that yellow fever is never epidemic in such localities.

RICHARD WAGGENER, M.D.

NAVAL PROVING GROUND, INDIAN HEAD, MD.

REDUCTION OF A SHOULDER DISLOCATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Recently, in consultation, I reduced a shoulder dislocation which had resisted the most varied manipulation for several hours, by the following method: Having passed a strong, folded towel through the axilla, and requested the attending surgeon to hold the arm firmly against the patient's body, I administered a few drops of chloroform. Then, having placed a foot against the coracoid process (the shoe having been removed), I made traction on the ends of the towel, and instantly reduced the dislocation completely and easily. I do not think the chloroform aided in the reduction. Very little force was required. If I had a similar case again, I would try the same method without chloroform. This method may have been employed thousands of times, but it was new to me. It served me well, and I hope it will serve others likewise.

J. W. KALES, M.D.

FRANKLINVILLE, N. Y.

TREATMENT OF WOUNDS WITH TINCTURE OF IODINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In your issue of August 3 you published an article by Dr. Carl Beck, on the primary treatment of infected wounds with tincture of iodine. I would like to call the doctor's attention to a work that may have escaped his notice. In 1895, Kocher and Tavel published a book, entitled, "Vorlesungen ueber chirurgische Infections Krankheiten" (Basel und Leipzig). In the first volume, they deal with infections caused by staphylococci, for which they use the term staphylomycosis. On page 211, under treatment of wounds infected with staphylococcus, they say (translated from the German text): "We found solutions of carbolic acid, even in the strongest concentrations of five per cent., insufficient, and advise either the frequent application of tincture of iodine, or the packing of every small incision with a piece of gauze saturated in tincture of iodine, to be changed every three hours." Later on: "Necrotic tissues have to be removed with forceps and scissors, and as long as they stick they must be moistened with tincture of iodine or nitrate of silver, in order to lessen the possibility of decomposition (um ihre Zersetzungsfaehigkeit zu verringern)." So also on page 180, when speaking of the treatment of furuncles: "Under ethyl-chloride spray an incision is made into the furuncle and the wound is painted with tincture of iodine."

ARTHUR STERN, M.D.,

Surg. to the German Hospital.

ELIZABETH, N. J.

Inconvenience to England Caused by Our Immigration Laws.—A great increase is reported in the [illegible] population of London for the last year, due to the immigration of Russian Poles, Italians, and Roumanians. Many of these are poor and helpless, and upon arriving in London en route for the United States, are refused passage by the consular agents and the steamship authorities. The question is to be brought up in Parliament as to how large a portion of these persons can be allowed as unfit to be received in America, were left last year in London, their own countries refusing to take them back.—*Chronicle.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, August 15, 1901.

The Origin of Oxalic Acid from Protein and Protein Derivatives.—Arthur E. Austin draws the following conclusions from experimental investigations: (1) That oxalic acid is derived from the carbohydrate group in albumins, presumably through the intervention of glycocoll by a process of splitting, through which the remainder is converted into urea—a vital process, though imitated by strong oxidizing agents; (2) that oxalic acid may also be derived from uric acid by fermentative action and oxidizing agents, and perhaps also by vital process; (3) that oxalic acid, present in many organs of the body, practically absent in the fæces of animals fed on foods not containing oxalic acid, yet ever present in the urine after long periods of fasting, may rightly be called a metabolic product and rightfully take its place with acetone, lactic, acetoacetic, and oxybutyric acids as a measure of abnormal retrograde metamorphosis.

Bile in the Abdominal Cavity.—John F. Thompson reports the case of a man in whom was found a large fluid accumulation in the abdominal cavity, two or three days after he had been thrown from a cart against a stone wall. Aspiration secured five quarts of apparently pure bile, and was repeated seven or eight times in three weeks, each time removing several quarts of bile. The patient's condition becoming serious, operation was performed, and the abdomen evacuated of four quarts of bile. The intestines had been crowded up against the liver, and were strongly adherent to that organ and other neighboring structures. A drainage tube was inserted. The flow of bile gradually ceased, the sinus closed, and the patient is now well and doing farm work. The exact point from which the bile came is not known, but it is probable that one of the man's fractured ribs may have injured the liver, or possibly the injury was direct. The case illustrates the tolerance of the peritoneum to adverse influences.

Medical News, August 17, 1901.

Fibroma of the Mesentery.—J. B. Murphy reports a case with successful operation. Twenty-four inches of ileum were excised with the tumor and end-to-end union made with button No. 3; the button was passed on the twelfth day. Fibroma of the mesentery is rare, there being only eleven other cases reported. The gravity of the operation in these cases depends upon the extent of the intestinal resection; the immediate dangers from the operation are shock and hemorrhage from the mesentery.

Acute Peritonitis; Its Treatment upon an Etiological Basis.—C. D. Hell regards acute peritonitis as a secondary condition due to germ infection, though the entrance of such infection may not always be demonstrable. The place of entrance of the infection into the peritoneum often determines the degree of inflammation. Regarding peritonitis as a secondary condition, the treatment must be along the lines of prophylaxis and elimination. The opium treatment has been superseded by catharsis, which should be instituted at the beginning of the infection; the weakness must be met by the usual stimulants and the tympanites relieved by use of the rectal tube. Cases of disseminated peritonitis are best treated by operation early in the disease, allowing cleansing of the peritoneum. Serum therapy has been of value in this type of the disease, and there is yet more to be hoped for along that line.

The Etiology of Melancholia. H. H. Stoner believes that melancholia is due to a disturbed balance between anabolic and katabolic tissue metabolism. It is an emotional disease, wherein the emotions are of a painful character, and the emotions he regards as wholly dependent upon the vegetative functions. According to this observer the cortical cells, or psychical neurons, functionate normally in melancholia; the quality of the sensation depends on the kind of stimulus inducing it; the quality of the sensation in melancholia is invariably painful, consequently it is due to the normal interpretation by a healthy cell of an abnormal stimulus. Assuming that a stimulus which enhances the metabolic process produces pleasurable emotions, and one which inhibits the process calls forth painful emotions, it is inferred that undue destructive metabolism is the abnormal stimulus referred to. The mental depression is explained by the patient's being absorbed by the painful emotions; that the psychical cells are not at fault is shown by the fact that the patient can be roused to the appreciation of other stimuli. The author considers that the successful treatment of melancholia goes to prove the validity of his

theory, as the only successful treatment tends to the re-establishment of the normal balance between constructive and destructive metamorphosis.

The New York Medical Journal, August 17, 1901.

Hot Air as a Therapeutic Agent.—Orrin S. Wightman thus sums up the advantages of this form of treatment: (1) Dry heat is a valuable pain reliever, without any of the depressant effects common to drugs. (2) In connection with constitutional and medicinal treatment, we have in it a positive curative agent. (3) It is a stimulant to rapid repair and absorption. (4) It is one of the most valuable eliminative agents we possess. (5) When indicated, it possesses a sedative action on the nervous system obtained by no other means.

Infection Spread by Domestic Pets; Resemblances between Diseases of the Lower Animals and Those of the Human Subject.—William B. Meany gives a number of examples of the transmission of diphtheria from animals to human beings, and *vice versa*. A disease has been observed in swine, sheep, horses, cattle, and dogs, which appears exactly similar to human diphtheria. The ratting and mousing propensities of dogs and cats make them especially liable to infection. It is supposed that pneumonic plague was spread on board the steamship *Friary* at Hull, January, 1901, by a cat taken on at Alexandrina, Egypt, which showed signs of illness during the voyage. It had frequented the forecastle, and only the men who lived in the forecastle succumbed to the attack. There were eight of these.

Dysentery in the Philippines.—M. H. Bowman says that investigations have shown that dysentery as seen in the Philippines is not a single, but two distinct and separate diseases. Acute dysentery is caused by the bacillus of Shiga. Its fatal result is due to inflammation of the bowel, rapid elimination of the watery fluids of the body, toxæmia, and exhaustion, much after the manner of cholera. Amœbic dysentery is caused by an amœba, and differs from acute dysentery anatomically, pathologically, and etiologically. It produces ulcers in the colon, and lesions in the liver. Medicine does not seem to influence the course of acute dysentery. Quinine solution is a specific for the amœbic dysentery, but its employment in rapid, acute, ulcerating cases is fraught with danger, and from the nature of the lesions it cannot be retained for a sufficient length of time to produce beneficial effects.

The Present Status of the Surgery of the Prostate.—William N. Wishard considers that operative procedures are of the greatest value when undertaken early, and that when they are long-deferred, serious resultant bladder, urethral, and renal diseases make the outcome increasingly dangerous. When the catheter has failed to give adequate relief, death is reasonably certain to occur ere long, especially in cases where the urethra has greatly increased in length by the elongation of its prostatic end, unless the suprapubic opening for either prolonged drainage or for the removal of the obstruction is done. If the symptoms are not severe, and are not amenable to the catheter, and if the length of the urethra from the meatus to the point where the urine is obtained does not exceed nine inches a perineal opening usually affords opportunity for stretching the entire length of the prostatic urethra, for dividing the small collar-shaped growths around the bladder end of the canal, and for removing the small projections by the finger, forceps, or cautery. In view of the serious dangers involved, many cases should be subjected to nothing more than the formation of a suprapubic channel, as suggested by McGuire and modified by Morris.

Journal American Medical Association, August 17, 1901.

Two Cases of Suppuration of the Parotid Gland with Pus in the External Auditory Canal.—Francis R. Packard reports two cases, which possess interest from the fact that in each case there was considerable difficulty in eliminating suppurative otitis media as the cause of pus in the auditory canal. Both cases were children, and the presence of the pus might be accounted for by infiltration through the incisuræ Santorini. The first patient a child of nine months, had a gummatous mass in the parotid gland and surrounding tissues, and was relieved by incision and specific treatment. The second case was a fatal one of measles and pneumonia, complicated by the parotiditis.

A Case of Multiple Gangrene Associated with Cholangitis and Adenoma of the Liver Complicating Typhoid Fever.—Isaac A. Abt reports such a case occurring in a child of twenty-one months. The gangrene, in areas varying in size from a pin-point to a silver quarter, and showing in the various stages papule, pustule, and ulceration with gangrene, were distributed over the anterior surface of the neck, the lower portion of the face, the lateral aspect of the thorax, and the entire back, as well as the inner surface of the thighs and the upper third of the legs. This condition occurring during or directly after typhoid fever is extremely rare. Catarrhal cholangitis was also found in this case, and adenoma, both rare occurrences.

The Diagnosis of Typhoid Fever in the Laboratory.—John Lovett Morse first protests against the separation of laboratory and clinical methods in the diagnosis of this disease, both being necessary, and then describes the various laboratory tests. They are the Widal reaction, examination of the fæces, the urine, and the blood for the typhoid bacillus, examination of the rose spots, the diazo-reaction, the leucocyte count, and tests which show the presence or absence of other diseases—such as examination of the blood for the plasmodium malariæ and lumbar puncture when there is question of meningitis. Laboratory methods must be used with due recognition of their value and of their limitations, otherwise they may lead to erroneous conclusions. The Widal reaction and the leucocyte count are the most useful; they are easily carried out and are within the reach of all. Certain other methods are of equal or even greater value, but are impracticable for every-day use.

Symptoms of Typhoid Fever in Infancy and Childhood.—J. P. Crozer Griffith says that the symptoms of this disease in children often differ materially from those occurring in adults. As to the onset, the walking typhoid is the rule in children, but there is also a sudden form of onset characterized by vomiting and by decided fever from the start. The duration of the disease is distinctly shortened, about seventeen days being the average length. Abortive attacks lasting a week are common. The mortality is less than in adults, especially under five years of age. Typhoid roseola is nearly as frequently present as in adults; enlargement of the spleen is probably always present; the temperature often arises without the usual step-like ascent. The fall may be almost critical. The tongue is not very liable to become dry, except in older children; vomiting may be troublesome, but diarrhœa is usually absent. Hemorrhage is of rare occurrence. There is a tendency for the nervous symptoms to predominate over the intestinal. There may be a pseudomeningitis at the beginning.

American Medicine, August 17, 1902.

Some Observations on the Treatment of Acute Insanity in General Hospitals.—Daniel R. Brower notes the following defects in the public institutions for treatment of the insane. Most of them are too large; they are too far from the homes of many patients; admission is by a cumbersome method, and many of them are in the hands of politicians. He believes that many acute cases of insanity can be cared for in general hospitals, admission being limited to cases of mania, melancholia, and stuporous insanity. Such patients should not be retained longer than six months unless well on the way to recovery. Admission to the general hospital wards should be free to the insane as to those afflicted with other diseases.

A Case of Gastritis Complicated by Myasthenia Gastrica, with Remarks on Weakness of the Gastric Muscle.—Edwin Zugsmith reports a case with recovery. Myasthenia may be caused by local and general overwork, may follow the acute infections and accompany certain chronic diseases. There are two forms, stagnation and retention, the dividing line being the presence or absence of food particles in the stomach before breakfast. Prognosis depends on the degree of the trouble and the extent and nature of the complications. In the mild forms a complete cure can be established. Treatment should be influenced by the reaction of the patient, the diet and the habits of life being carefully controlled. Intragastric electricity, and local and general massage are useful. If the patient continues to retrogade in spite of vigorous, persistent treatment of this sort, gastroenterostomy should be performed.

A Study of the Hemorrhoidal Circulation with Special Reference to the Prevention of Bleeding after Radical Operations for Piles.—Will B. Davis believes that the hemorrhoidal arteries do not enter into the formation of piles and that they contribute little, if at all, to post-operative hemorrhages. He agrees with Verneuil as to the active cause of piles and bases his explanation of post-operative hemorrhage on the same factor, believing that thorough divulsion—from anus to ampulla—preliminary to operation will prevent the bleeding, or if not done before operation and hemorrhage does occur this divulsion will check it. He strongly recommends this practice since after thorough divulsion the muscular wall of the rectum will not recover its contractility suf-

ficiently to embarrass the veins in their blood-returning function by compressing them at their points of exit until the healing process is fairly complete.

Philadelphia Medical Journal, August 17, 1901.

Oil of Pennyroyal as a Remedy Against Mosquitos.—V. H. McKnight calls attention to the fact that oil of pennyroyal is antagonistic to mosquitos; the insects avoid persons who have this oil about them.

Progressive Hardness of Hearing and Its Arrest by Surgical Removal of the Incus.—Charles H. Burnett believes progressive hardness of hearing to be due to an "affection of the nerves supplying the middle ear and correlated structures." He has operated upon twenty-five cases prior to 1892, and considers that incudectomy arrests progressive deafness not only in the operated ear, but in the opposite ear, if it has appeared there, and is prophylactic if the other ear is not yet affected. Since 1892 he has operated upon fifty-three cases, the results of which, however, he has not yet published.

The Difficulties Attendant upon the Proper Treatment of Diseases of the Ear in Dispensary Practice.—Francis R. Packard calls attention to the very patent obstacles to proper treatment in dispensaries, such as the class of persons treated—foreigners unused to cleanliness and unable to comprehend directions, lack of time due to overcrowding of patients, the difficulty of keeping records of cases owing to lack of time, and inadequate armamentaria. He thinks much of the trouble comes from the fact that the hospital managers know nothing about the practical management of a dispensary, and urges that every physician who works in a special institution should insist upon having dispensary work as carefully provided for as the work in the wards.

A Nosological Study from a Clinical Standpoint of Certain Manifestations Accompanying and Following Malaria.—G. W. Penn believes that no one, seeing a case of continued malarial fever, so called, during the late summer and fall months, can tell within one to seven weeks its duration. He believes the unknown fever of the South is a sequence of estivo-autumnal fever in individuals whose condition is such as to permit the persistence of the toxemia after the germs have been destroyed—in other words, is a post-malarial fever. In these cases after the first week or two quinine is inefficient, and examination shows the absence of malarial hematozoa. He recommends laboratory investigation along the line of serum therapy for the treatment of this condition, which is common throughout the Southern States.

The Lancet, August 10, 1901.

Pasteurization of Infected Milk.—E. Sydney St. B. Sladen says that the danger of using milk containing microorganisms that cause scarlet fever, typhoid fever, diphtheria, and consumption is diminished by heating it to 80° C. and keeping it at that temperature for ten minutes. If the milk is heated to 85° C. all such danger appears to be removed. The author gives statistics in regard to the temperature and time required to bring about the death of, or to inhibit the action of the tubercle bacillus. He also furnishes clinical evidence of the transmission of tuberculosis by milk. Professor Bang states that by a short heating at 85° C. the tubercle bacilli are killed, and it immediately afterwards the milk be well and rapidly cooled its loses its cooked taste. Excellent butter can be made with cream that has been heated to 85° C.

On the Physiological Cure of the Morphine Habit.—W. Oscar Jennings pursues the following plan of treatment which reduces the craving and thus destroys the habit with the minimum of suffering. He proceeds as fast as possible, but as slowly as necessary to effect a cure without distress. In the first place he substitutes rectal injections of morphine for the hypodermic injections, which give an even sedation instead of a fascinating stimulation. For the heart depression which always follows reduction sparteine is given. For the next factor in the craving, hyperacidity of the stomach and organism generally, bicarbonate of sodium is administered. The last of the author's therapeutic triad is the hot-air bath, which is tonic and sedative, and may also act as an eliminator of some exciting of craving. A moderate and as a rule non-alcoholic diet is insisted on. For insomnia galvanization may be magical, but if unsuccessful some hypnotic must be given. Exercise and Turkish baths will assist in preventing the return of cravings. The author reports several cases successfully treated in the manner described.

Curious Symptoms after Administration of Nitrous Oxide for Dental Extraction.—A. Stanley Green administered gas to a man of twenty-six years, using Barth's inhaler and allowing plenty of air. Complete anæsthesia was easily produced and four teeth were extracted. A few minutes after recovering consciousness the patient complained of numbness in hands, legs, and feet. The hands were pronated, the fingers slightly flexed and the thumbs strongly adducted. Rubbing caused pain. Respirations became rapid, and accompanied by sighing and then stridor. The pulse was 84, the color was good. The patient was excessively restless and unable to articulate. The symptoms gradually subsided and after an hour's rest the patient was sufficiently recovered to return home. He was not at all of an hysterical temperament. The author has administered gas more than 1,000 times during the past three years and has never before met with such a case.

British Medical Journal, August 10, 1901.

Plague and Its Prevention as a Disease Communicable from Animals to Man.—David Samuel Davies, in view of the fact that the plague is known to be a rat-borne disease, advocates an international agreement to the effect that merchant vessels shall destroy rats on board before loading and discharge, and that uniform steps be taken to prevent intercommunication between ship and shore rats at times of loading and discharge. A resolution to this effect has been passed by the British Chamber of Commerce, and will be presented at the next meeting of the Associated Chambers of Commerce.

Berliner klin. Wochenschrift, July 29 and August 5, 1901.

Tabes in Women.—P. Fehre's analysis of forty-one cases of this disease in women leads him to believe that the etiological and predisposing factors found in men are equally active with the other sex. In all instances syphilis plays an important rôle either as a direct or indirect cause, while the puerperal state can at least aggravate the disease. The spread of syphilis and the increased participation of women in affairs seems to have brought about a relative and absolute increase in the number of female tabetics.

Chronic Pentosuria.—F. Meyer describes the case of a middle-aged man whose urine, on examination for life insurance, was found to give a well-marked reaction to both Trommer's and Moore's tests. The diagnosis of diabetes mellitus was accordingly made and the patient subjected to a course of treatment. A subsequent polarization test was negative, and so he was declared cured. Six years later he came under the observation of the author complaining of emaciation, weakness, headache, and neuralgic pains in the extremities. Some constitutional disease was suspected and the uranalysis gave positive results with Trömmer's and Moore's tests, but the fermentation and polarization tests were negative; so pentosuria was suspected, and its presence was confirmed by the orcin reaction. Several methods of treatment, such as rigid diet with Carlsbad cure, moderate diet with some carbohydrates, and a wholly unrestricted diet, were all ineffectual in reducing the amount of pentose excreted, but finally a régime of milk and definite quantities of carbohydrate caused great general improvement with a diminution of the pentose to one-half the former amount. The emaciation, neurasthenia, and obstinate neuralgia appear to be the most prominent features of the disease and the favorable effect of a mixed diet is noteworthy.

The Frequency of Herpes Zoster.—E. Hoennicke has collected a series of statistics which lead him to conclude that herpes zoster makes about one per cent. of all skin diseases. Both sexes are affected equally but it is especially a disease of youth, occurring most frequently between the ages of fifteen and thirty and being rarely observed in early childhood and old age. In general those regions of the body are most often affected whose nerve trunks possess the largest number of branches, but the trigeminal domain is an exception to this rule, perhaps owing to its greater risk of exposure to injury. The disease shows no preference for either side of the body, though bilateral herpes is rare. Physicians and attendants on the sick are apt to suffer during epidemics but there is no other calling exhibiting a predisposition. While sporadic zoster occurs all through the year, the spring and fall are the seasons of the epidemics.

Puerperal Psychoses. E. Meyer has found that of 1104 female patients that have been treated in the clinic of psychiatry at Tübingen, in 51 cases the disease began during the puerperium or lactation. Of these, 11 were melancholia, 4 periodic melancholia, 3 circular psychoses, 5 paranoia, 9 acute dementia (verwirrtheit), 14 katatonia, 2 hebephrenia, 2 epilepsy, and 1 hysteria. A study of these cases did not reveal any specific puerperal psychosis, and none of the pictures differed from types of the diseases depending on the ordinary etiological factors,

neither was it possible to detect any particular tendency referable to their puerperal origin. The prognosis is the same as that of the usual types of the diseases.

Enuresis in Childhood.—M. Thiemich considers the nocturnal incontinence of children not as a local trouble to be grouped under the diseases of the uropoietic system, but as a manifestation of hysteria. In adopting this view, it is necessary to take into consideration the fact that the hysteria of children differs from that of adults in being essentially monosymptomatic, without the presence of the usual stigmata, and the author holds that the good results following such measures as removal of adenoids, injections of strychnine into the mons veneris, elevation of the pelvis, etc., are to be ascribed solely to their suggestive effect. The most efficient measure is the employment of a strong faradic current, which is not necessarily to be applied to the abdomen, but is just as efficient if one pole is placed over the sternum and the other passed over the arms. Care must be taken not to convey the impression that the treatment is a punishment, for such methods are notoriously inefficient, but it is to be explained that, even although painful, the measure is certain, and that a second or third application is always successful; if tactfully conducted, more than a single session is rarely required. Removal from home and isolation, in this as in all forms of hysteria, are the most potent of all remedies, and, while usually difficult to carry out in these cases, may be reserved as a last resort. A somewhat analogous condition is that of "pollakuria," in which small quantities of urine are frequently voided through the day, and this also usually yields readily to the electrical treatment.

Human and Bovine Tuberculosis.—R. Virchow assumes an attitude of conservative but tolerant and hopeful agnosticism towards Koch's recent utterances at the British Tuberculosis Congress. Lister's note of caution receives recognition and due prominence is given to the fact that the converse experiments on man are still lacking. Any suspicion, however, that the preparations of the Berlin Veterinary Institute prepared by Schötze under Koch's supervision were inconclusive is groundless, and it was satisfactorily demonstrated that infectious matter taken with great care from human consumptives did not in the animals experimented upon produce any lesions comparable to those of bovine tuberculosis. Koch's statement that human tuberculosis and that of cattle are different, and that the former cannot be transferred to these animals does not surprise the author, since he himself long ago expressed the opinion that this difference existed, while it must be admitted that the second half of the theorem has now been definitely proven. In the consideration of these problems, it is especially important not to lose sight of the fact that a tubercle is not any haphazard thing that may happen to contain tubercle bacilli, but is a definite anatomical structure consisting of cells that have developed from the living body, and the tubercle bacillus is no constituent element of this structure. This distinction has unhappily been too often disregarded, with much resulting confusion. Another question which has not received sufficient consideration is that of quantitative bacteriology. The detection of a single cholera or typhoid bacillus is usually heralded as evidence of the existence of other countless millions, but the subject still requires much study, and the author believes that unless a certain quantity of bacilli has been introduced into the body the risk is not great.

Muenchener medicinische Wochenschrift, July 30, 1901.

A Subjective Symptom in Pericarditis with Effusion.—P. Pregowski observed that while he was suffering from a pericardial effusion whenever he attempted to lie on the right side he had the sensation of something pressing on the mediastinum and downward, *i. e.* toward the right side. This he ascribed to the pressure exerted by the fluid in changing the position.

Oleum Cinereum in Syphilis.—Maul finds that this is one of the safest and most agreeable antisyphilitics, and mentions two cases in which intragluteal injections of ten to fifteen grams were given without any unpleasant symptoms. It is not necessary to warm the remedy before injection, but it should be prepared exactly according to Neisser's formula, and sterilized.

Cotton Swabs in Eye Practice. O. Neustatter recommends cotton swabs made by twisting a bit of absorbent cotton about the end of a match or glass rod instead of the ordinary camel's-hair pencils in use. If the latter are used, one must be kept separately for each patient, and even then it should be sterilized after use. This is an expensive and troublesome method, while the swabs are absolutely sterile and cheap, and in infectious cases can be burned immediately. All the requirements of such an instrument can be fulfilled by modifying the shape and degree of firmness given to the cotton, and every use for which the brush is adapted is better served by this substitute.

Specific Blood Changes after Urine Injections.—A. Schattenfroh reports positive results of his experiments to determine whether the injection of urine of an animal into one of a different species produces specific changes in its blood. A large number of rabbits received subcutaneously in divided doses 120–150 c.c. of human, goat, or horse urine, the injections being repeated at intervals of two to three days, until the entire amount had been given. The serum of the animals treated with human and goat's urine acquired strong solvent and agglutinating properties for the red cells of the animals in question. This action was especially well marked in serum prepared with human urine. Control tests with active and inactive goat serum produced in the rabbits large amounts of "anticomplements" and "precipitins," while hæmolytic bodies were entirely absent.

Vaginal Exploratory Puncture and Incision.—H. Franz gives a résumé of the opinions of various authorities which shows that the value of this procedure is still far from settled. Many commend it as a useful diagnostic measure, while others discard it as dangerous and unreliable. At Fehling's clinic eighty-one cases have been subjected to it, with very satisfactory results. The diagnosis was confirmed by the exploration in fifty-six cases; in ten cases the evidence so obtained caused the diagnosis to be changed; six times the results were doubtful, and in four cases nothing was gained. The conclusion is that vaginal puncture is a valuable aid in the diagnosis of tumors situated in the *cul-de-sac* and causing protrusion of the posterior fornix. It is especially adapted for the differentiation between tubal tumors, either of inflammatory nature or arising as ectopic pregnancies, and pelvic exudations. Scrupulous asepsis in all points is to be observed. Vaginal section may advantageously be added to the puncture. The needle should be sufficiently long and of large caliber, and is plunged into the lowest and most fluctuating part of the tumor. The cervix is then drawn upward and forward making the posterior vaginal wall tense, and the mucosa is incised close to the needle. A dressing forceps may then be easily plunged into the tumor, and by the opening of its jaws the aperture is enlarged sufficiently to permit the escape of the fluid. The cavity is packed with iodoform gauze and drained with rubber tubing, through which irrigation may easily be performed.

Deutsche medicinische Wochenschrift, August 1, 1901.

Some Cardiac Affections without Organic Disease.—Th. Rumpf describes a case of "wandering heart" occurring in a man of thirty. In the erect posture nothing abnormal could be detected by auscultation or percussion, but changes of position produced marked alterations. With the patient on the right side, the apex was displaced outward, while, when he was lying on the other side, it was moved to the sixth interspace, close to the left border of the sternum, the whole distance traveled being about four and one-half inches. The anomaly developed after an obesity cure which reduced his weight eighty-six pounds, and the relaxation of the abdominal walls so produced supposably allowed a similar laxity of the diaphragm which deprived the heart of its normal fixation. An analogous disturbance depending on an elevation of the diaphragm is the palpitation following the accumulation of gas in the stomach, or, more rarely, the colon. The symptoms so produced may go on to intermittency of the pulse, elevation of the cardiac dulness, oppression, and pain, all disappearing as soon as the flatus has been discharged. Another functional lesion is the so-called "stumbling heart," which consists in an intermittence depending on the occurrence of a second systole close on the first, without the intervention of a complete diastole.

A Typhoid-like Disease Produced by a Hitherto Undescribed Organism (Bacillus Bremensis Febris Gastricæ).—Kurth describes some observations made in Bremen during the summer of 1900, which, perhaps throw some light on the affection known to the older clinicians as gastric fever, and which also may explain the definite percentage of cases of typhoid fever in which the Widal reaction remains negative. In examining the stools of a suspected typhoid patient, an organism was detected which strongly resembled, but was not identical with Gartner's bacillus enteritidis and which gave a strong (1-500) serum reaction with blood taken from another patient, who also did not give a Widal. In the course of the summer, five cases were observed in which the same bacillus could be demonstrated and the serum reaction obtained, while no agglutination was produced with typhoid bacilli. The organism is a highly motile rod of the size and form of a typhoid bacillus, and is provided with

numerous flagella, and does not stain by Gram's method. It is highly virulent for guinea-pigs and white mice, which die within twenty-four hours after inoculation. The course of the temperature in the cases described is very irregular, and does not present the usual appearance of a typhoid curve.

French Journals.

Complete Traumatic Rupture of the Urethra.—Walther reports a case of this kind. The patient fell astradille, completely rupturing the urethra. Walther saw the case fourteen hours after the accident. In a perineal incision he found the ends of the urethra which had been separated several centimeters, and he reunited them by a suture in three places. The operation resulted in union by first intention. Recovery was uneventful, and the patient has not suffered at all from contraction of the urethra.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, July 4, 1901.

Value of Experiments with Salol in the Clinical Study of the Functions of the Pancreas.—P. Nobécourt and Prosper Merklen draw the following conclusions from their investigation of this subject. The property of splitting up salol is not limited to the pancreas alone, but the bile and all the mucosa of the digestive tract possesses the same action. It is, however, probable that this breaking up of salol does not take place in the stomach on account of the acidity of the gastric juice; it occurs, indeed, only in the presence of an alkaline or neutral medium, and a very feeble acidity suffices to prevent the action. Clinically, then, the use of salol has no value in the exploration of the functions of the pancreas.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 13 1901.

The Heart in Typhoid Fever.—According to M. C. Bacaloglu, typhoid pericarditis may exist alone; oftener, there is an endopericarditis. Anatomically, the pericarditis may be purulent; it may be dry, adhesive, while sometimes there is effusion which is rapidly reabsorbed. In a case observed by Bacaloglu, a smear of the pericardial fluid showed the presence of the bacillus of Eberth. Besides, this worker has produced experimentally pericarditis by the injection of this bacillus. Endocarditis is generally localized on the mitral or bicuspid orifice, more rarely on the tricuspid or pulmonary orifice. It may be due to various microorganisms or to the bacillus of Eberth. This affection has been reproduced experimentally with the typhoid bacillus.—*Gazette des Hôpitaux*, July 9, 1901.

Asphyxia and Apparent Death by Hanging; Resuscitation by Rhythmical Tractions on the Tongue.—Camille Joubert reports the case of a young man of eighteen years, who, in a state of acute alcoholism, tried to commit suicide by hanging. When the writer reached him, he found two attendants rubbing him vigorously with brandy, but in vain. The place where the patient was rescued was so contracted that it was impossible to apply the ordinary methods of artificial respiration. With a hemostatic forceps, the tip of the tongue was seized, and rhythmical tractions of this organ were begun. In about twenty minutes the patient gave a rather noisy inspiration. The efforts were then suspended for an instant, and the breathing ceased. Again, after about six minutes of renewed effort, respiration was re-established regularly and definitely.—*La Tribune Médicale*, June 12, 1901.

Torsion of the Pedicle of Ovarian Cysts.—Albert Martin believes that this accident occurs much oftener than is known. Clinically, the symptoms vary according as the strangulation is complete or incomplete. In the first instance, there is violent abdominal pain which occurs suddenly, while the general condition becomes rapidly bad. The facies becomes haggard, the pulse frequent, the respiration irregular, and there is nausea with vomiting. If the tension is complete, a true peritonitis supervenes, with all its alarming symptoms. In complete torsion the symptoms are less severe, and death comes more slowly. This affection may be confused with hepatic or nephritic colic, with strangulation of the bowel or volvulus, or with the rupture of a tubal pregnancy. In such cases an exploratory operation will be the only means of clinching the diagnosis. It is much safer for the patient to explore the abdomen than to temporize, for operation will save many lives that would otherwise be sacrificed.—*Revue Médicale de Normandie*, July 25, 1901.

Metastatic Ophthalmia of the Left Eye; Serpiginous Ulcer of the Right Eye; Bilateral Conjunctivitis in a Patient Suffering with Pneumonia.—Petit and Chevallier describe the case of a woman, seventy-nine years old, who was brought to the hospital suffering from an attack of pneumonia. Eleven days later, a conjunctival secretion was discovered in the left eye. The eye grew worse, and the affection spread to the right eye. Within five days the conjunctival secretion was very much less, but an ulcer developed on the right cornea, involving almost its upper half. The iris was covered with exudate and contracted. There was slight hypopyon. The left eye began to show exophthalmos. There was marked chemosis; the eyelids were œdematous. The cornea was opaque. There was slight hypopyon, and the tension was slightly increased. The movements of the eyes in all directions did not seem to cause pain. Finally, the right cornea was perforated in the center. A month after the patient's admission to the hospital, almost every inflammatory symptom had disappeared from the left eye. In the right eye there were symptoms of panophthalmia, intense chemosis, exophthalmos, etc. Microscopical examination after death revealed numerous encapsulated diplococci. The pus from the ulcer showed many lanceolate diplococci. From smears of the conjunctival secretion on agar there grew numerous colonies of pneumococci; and from the pus of the ulcer there were pure cultures of the pneumococcus. The infection probably spread to the eye by way of the lacrymal passages and by the nasal fossæ.—*La Revue Médicale de Normandie*, June 25, 1901.

Diagnosis of Scarlatina.—G. Variot states that while measles may be suspected with some degree of certainty in the period of invasion on account of the more or less prolonged catarrhal phenomena which precede, this is not the case with scarlatina, the period of invasion of which is very rapid and the onset sudden. In normal scarlatina of moderate intensity, the most frequent form, there is a triad of symptoms which makes the diagnosis of the disease almost absolutely certain; the association of fever, angina, and erythema, appearing after twenty-four or thirty-six hours, forms a complete clinical picture, the features of which are very characteristic. The eruption is at first generally observed in the groins, on the abdominal wall, over the upper part of the thighs, on the sides of the thorax, and in the axillæ. When still more developed, the exanthem is indeed characteristic; it appears at a little distance to be a diffused redness, but on examination with a magnifying glass, it is seen to be made up of tiny elevations on the skin which are not always perceptible to the touch. The skin between these points is of a less deep tint. The existence of malignant scarlatina is shown by extreme hyperthermia (41° C. and more), by delirium, and by unusual agitation. The nervous disturbance is most alarming. Isolation of scarlatina should always be practised.—*Journal des Praticiens*, July 20, 1901.

Clinical Examination of the Cerebrospinal Liquid.—Ch. Achard presents a most interesting paper on this subject. After puncture, the liquid generally flows out, drop by drop, sometimes very slowly, sometimes more rapidly, and now and then it will come out in jets, as it does when a pleurisy or ascites is punctured. The quantity of liquid withdrawn varies. This liquid is normally perfectly limpid, colorless, and clear as water. In jaundice it is of a yellowish tinge. Exceptionally, when jaundice is not present, it looks like clear urine—having an amber tint; the cause of this is not well understood. In acute meningitis, it becomes cloudy, milky sometimes, and even purulent, with a greenish shade. This liquid may be bloody. This has been observed in scurvy, in cerebral hemorrhages, and in those of the spinal meninges. Allowed to stand, the normal cerebrospinal liquid has no sediment. In acute or chronic inflammation of the meninges it is flocculent, the tiny particles resembling grains of sand. In suppurative meningitis there is a rather thick, purulent layer. As to the density, the writer has determined it to be normally from 1.003 to 1.004, while in morbid conditions it varies between 1.002 and 1.000. As to the permeability of the spinal serosa, it seems that it is truly elective for certain normal crystalloid substances of the blood, and offers an insuperable obstacle to the passage of substances foreign to the normal composition of serum. The cerebrospinal liquid contains in every 1,000 parts from 990 to 980 c.c. of water, and 6 c.c. of chlorides. There have also been found small quantities of phosphate and carbonate of lime, urea, in the majority of cases a substance which reduces Fehling's solution, and at times traces of albumin. Fibrin is found in meningitis. Peptones are found. Finally, bile pigments may be present. According to Concetti, bactericidal substances are contained in this liquid. The toxicity in the normal state is *nil*. According to certain writers, the cerebrospinal liquid, in the normal condition, does not contain cellular elements or at least only a few lymphocytes. The bacteriological study of this liquid is productive of very valuable results. Thus it may be seen that lumbar puncture may contribute much to the certainty of diagnosis, prognosis, and treatment.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, July 21, 1901.

Society Reports.

BRITISH CONGRESS ON TUBERCULOSIS

Held in London July 22-26, 1901.

(Continued from page 275.)

SECTION III.—PATHOLOGY, INCLUDING BACTERIOLOGY.

Third Day.—Thursday, July 25.

(The session of Wednesday was held in union with Section II—see p. 237.)

The Varieties of Tuberculosis.—Professor C. Benda of the Urban Krankenhaus, Berlin, opened this discussion. The tubercle bacillus, he said, is intracellular, it has a slow growth, and it causes severe local reaction in the tissues. These three qualities limit its dangers for the organism attacked whilst all three combined produce a localization of the germ of the disease. The bacillus may, however, spread through the body with the help of other factors of many kinds. In the organism in which the bacillus finds by means of development, tuberculosis goes very slowly on its continued course, and may remain localized for quite a long time, *e. g.*, in the lymph glands. In correspondence with the character of the development, tuberculosis progresses in the same organ, or attacks neighboring organs (ordinal metastases), or may pass on to a remote organ (distant metastases). In the spread of tuberculosis in the same organ, the epithelial canals, in which runs the excretory stream, play an important part. In the lungs the bronchioles, in the kidneys the urinary tubules, in the scrotum the "vasa epididymidis" and the "vasa efferentia," as well as the rete testis, are channels for the spread of the disease. Regional metastasis occurs chiefly through the epithelial channels and by the lymph vessels. The share of the mucous membrane in regional metastasis is recognizable in therespiratory, the digestive, and the urogenital apparatus. These canals spread the tuberculous virus not only in the direction of the excretory stream, but, with the help of antiperistalsis, also in the opposite sense, as from the prostate to the scrotum, or from the bladder to the kidneys. In remote metastases the epithelial channels come into consideration, as when infection of the bowels follows disease in the lungs. The blood vessels and the thoracic duct are, however, the most important factors in the production of remote metastases. The blood vessels serve not only as a means of development for the bacilli but also for the dissemination of the toxin. The clinical picture of acute miliary tuberculosis rests not only upon the dissemination of the bacilli and the development of the metastatic tubercles, but also and especially upon the toxemia resulting from poison formed in the blood-vessel tubercles.

Dr. D. J. Hamilton, Professor of Pathology, University of Aberdeen, said the chief portals by which the tubercle bacillus gains entrance to the human body are the lungs and the lower half of the small intestine. A primary tuberculosis of the stomach may almost be excluded, and the same may be said of that of the upper air-passages. Nevertheless the lymph-glands along the course of the upper air-passages and along the lower segments of the alimentary canal are common seats of a localized tuberculosis. The question thus arises whether the absorbents of the mucous membrane of these parts can take up the bacillus and hand it on to the glands without themselves becoming tuberculous. Having gained entrance to the body the bacillus tends to propagate along the lymphatics rather than through the blood-vessels, and the reason for this is probably that a great many bacilli are destroyed by the phagocytes in the blood. The pericardium is rarely tuberculous, even when all the other serous membranes throughout the body are affected. This he attributed to the peculiar power the pericardial fluid has for resisting the tubercle bacilli. He went on to consider the giant cells of tubercle and their meaning, the variety in the outward aspects of the lesions of tubercle, caseation of tubercles and its cause, and the absence of putrefaction from ulcerating tuberculous lesions.

Fourth Day.—Friday, July 26.

Mixed Infection in Tuberculosis.—Mr. A. G. R. Foulerton, bacteriologist for Middlesex Hospital, London, opened the discussion. He said that his remarks were limited almost entirely to the consideration of the part played by secondary infection in that form of tuberculosis in which the symptoms and signs are manifest, and in which the results of examination are, as it would seem, most exactly as they are found in chronic pulmonary tuberculosis occurring in a lung. For it may be indeed almost universally the case that the pulmonary tuberculosis and the pulmonary phthisis are used in clinical medicine as if synonymous with mean pathologically the two conditions differ widely, although agreeing in the fact that bacillus tuberculosis is present in the lesions of each. In uncomplicated chronic pulmonary tuberculosis the single organism present, the specific bacillus, is one which, under the given conditions, does not manifest more than quite a low degree of virulence in the majority of cases, whether as regards its direct action on the tissues actually infected, or as regards its action on the system as a whole by the production of toxins. In chronic pulmonary phthisis, on the other hand, to the action of this parasite is added the more acute influence of pyogenic organisms, whose potentiality for evil, again under the given conditions, is incomparably greater, whether by direct action on the tissues infected or by the production of toxins. In lower animals the conditions which correspond with general miliary tuberculosis and with chronic pulmonary tuberculosis can be produced at will according to the method of inoculation practised. If one causes a general blood infection by the injection of bacillus tuberculosis directly into a vein, the result is manifest in the development of a large number of gray miliary tubercles in the lungs—the common seat of arrest and lodgment of bacteria circulating in the blood—in the spleen, and elsewhere. The animal usually dies from the results of the infection before sufficient time has elapsed for the granulomata to undergo the degenerative changes found in cases of tuberculosis in which the degree of primary infection has been less intense. If, on the other hand, the animal is made to inhale infected dust, one sees a chronic, and at first strictly localized tuberculosis, such as is the first stage towards chronic pulmonary phthisis. Under these conditions, unless the initial dose of bacteria inhaled has been excessive, life is sufficiently prolonged for the resulting granulomata to undergo the successive degenerative phases seen in the lesions of chronic pulmonary tuberculosis in man. Practically all who have worked at the subject are agreed that various species of cocci are the predominating organisms in the secondary infection of tuberculous cavities. Streptococcus pyogenes, Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Diplococcus pneumoniæ, and Micrococcus tetragenus being found in the sputa fully. Amongst other bacteria of less common occurrence under these conditions are Bacillus pneumoniæ, Bacillus pneumoniæ of Friedlander, Bacillus pyocyaneus, Bacillus of Proteus, and Saccharomyces albicans. Sata also describes B. pseudo-diphtheriticus and B. pseudo-diphtheriticus pulmonalis as occurring with some frequency. Artault, again, has compiled a very full list of the bacteria which are found in cavities after death, but many of the organisms mentioned by him, and by others who have carried out this method of examination after death, must have been present as merely casual contaminations, and cannot be considered seriously as having had any definite influence on the course of the disease. It is to the pyogenic cocci, and above the rest to Streptococcus pyogenes, that we have therefore to look when considering the effects of secondary

infectious as exercised through the lymphatics of a case of chronic pulmonary phthisis.

Dr. WM. OPHÜLS, of San Francisco, after referring to the methods by which the subject had been studied, went on to say that the general opinion at present is that the effect of mixed infection in pulmonary tuberculosis is profound, some even ascribing all or nearly all the acute processes to it, though others, while not denying the occurrence, consider it of little importance. The truth lies midway between these two views, some pneumonic processes in phthisis being due to the tubercle bacillus alone, others to mixed infection. The speaker had studied thirty-nine consecutive cases of phthisis, to which he added one later case. A histological and a routine bacteriological examination of all the organs had been made. In the neighborhood of old cavities and scars was often found the condition called by Rindfleisch Inveterirtes Oedem"—indurated, airless areas of smooth surface. Bacteria were never found in these. Old tubercles are either disseminated or conglomerate. No bacteria, except tubercle bacilli, were found in these except in cavities in them. Tuberculous pneumonia was found in twenty-five cases—*i. e.*, a pneumonic process, lobular or fused, in which only tubercle bacilli could be found. The tubercle bacilli were present in large numbers where liquefaction of caseous areas was going on. The process was considered to be due to aspiration from cavities. In seven cases in which old cavities had been secondarily infected with pyogenic cocci, a more or less general infection had resulted, though no mixed infection in the lung. In two cases a late stage of infiltration of the pulmonary tissue with blood aspirated during a hæmoptysis was met with. In one, the bacillus tuberculosis was found in sections, and from one staphylococcus pyogenes aureus was cultivated. No example was met with in this series of the "kasige Mischpneumonie" of Sata *i. e.*, mixed infection with caseation; this, the author thought, was possibly due to climatic reasons, for he met with such cases when working in Germany. The course of phthisis clinically shows a primary stage of slow insidious development, succeeded by numerous exacerbations and remissions. These exacerbations are to be considered to correspond to the inhalation of infectious material from cavities into the bronchi. The result will vary according to the amount and nature—if there are many pyogenic cocci, an acute mixed infection will follow, which may develop into a kasige Mischpneumonie, or a more chronic condition leading to carnification. In many cases, the acute inflammatory process produced by the pyogenic cocci causes, if there are few, a localized lesion, if many, a tuberculous pneumonia. Probably many lesions which are found post-mortem to be purely tuberculous start as mixed infections; this opinion is supported by experimental evidence. This, however, is not true of all, for he finds cavities containing tubercle bacilli in pure culture.

Mode of Death.—In twenty out of the thirty-nine cases the immediate cause of death was acute mixed infection, or sepsis, originating from cavities containing pyogenic cocci. Of the remaining nineteen, in five only was death due to the extent of the pulmonary tuberculosis, in two the cause was acute infection of the pleura, in one, perforation of an intestinal ulcer, in four, the giving out of a moderately hypertrophied heart, or one fatty heart and myocarditis; in one, diarrhœa; in five the cause was obscure.

SECTION IV.—VETERINARY.

First Day—Tuesday, July 23.

SIR G. BROWN, C.B., Governor of the Royal Veterinary College, presided over this section.

Diagnosis of Tuberculosis in Animals During Life.—Prof. DEWAR, Principal of the Edinburgh Veterinary College, in opening this discussion, expressed his belief that cows with tuberculous udders were more numerous than is commonly supposed. The udders were affected in three per cent. of tuberculous cows. In seventy-five per cent. the thoracic organs were affected early. Tuberculin was the most reliable means of diagnosis, but it must be prepared by a competent pathological chemist and carefully tested before use. He pointed out the rules to be observed by the veterinary surgeon in testing a herd, and if all precautions were taken the results would be correct and definite in ninety-eight per cent.

Drs. NOCARD and MALM were equally convinced of the certainty of the results, and the latter averred that all his results had been confirmed by necropsies.

Dr. SCHUTZ pointed out that susceptibility to tuberculin had a latent period, rose suddenly, and fell gradually.

Dr. BANG, of Copenhagen, said that ninety-nine per cent. of the cows whose milk he had pronounced tuberculous on microscopical examination were found to have tuberculous udders.

Prof. MCFADYEAN held that bacteriology was essential for diagnosis, as this had to be determined earlier than in man. The tuberculin test at an early stage he found better than all others together, but it was not infallible. Artificially infected cows might show no reaction for fifty days.

Dr. HEYTEA had had only two per cent. failures with tuberculin.

Prof. OWEN WILLIAMS found the test almost infallible. He had expected to hear something of such sources of infection as dogs, cats, horses, birds, etc. Several other speakers agreed that tuberculin was the chief reliable test and when sources of error were excluded successful in ninety to ninety-eight per cent.

A communication by Prof. ARLOING of Lyons was read by the chairman. The author said that the serum of tuberculous animals gave the agglutination reaction in a dilution of $\frac{1}{10}$ to $\frac{1}{16}$, but in the non-tuberculous it required $\frac{1}{2}$ to $\frac{1}{4}$, and this test he found of special value when fraud had been resorted to in order to vitiate the results of tuberculin testing.

Second Day—Wednesday, July 24.

Milk Supply in Relation to Tuberculosis. Mr. J. A. W. DOLLAR, who opened the discussion, dealt with his subject in almost all its many aspects. He gave experimental facts that seemed inconsistent with Koch's statement regarding the transmission of bovine tuberculosis. He considered the rarity of primary intestinal tuberculosis was due to the fact that to infect the digestive tract there must be a degree of concentration of the bacilli. He warned the audience not to credit the common idea that goats are unsusceptible, for Prof. NOCARD had shown they could be infected by injecting tuberculous milk beneath the stripped udder. Tubercle also attacked sheep and asses.

The PRESIDENT remarked that Dr. Crookshank had produced tuberculosis in a calf by injecting phthisical sputum.

Mr. EATON JONES had great doubts about the propositions of Koch, and said the health authorities ought to go on protecting the public in every possible way.

Prof. YOUNG condemned the laxity of the authorities in the inspection of milk. He thought it would help much if they had the power to test dairy cows with tuberculin.

Mr. LAITHWOOD said it was easy to prevent disease through the milk supply. He recommended a State veterinary service such as Italy had established. He would include tuberculosis in the Contagious Diseases (Animals) Act, and not allow tuberculin to be used except by qualified veterinary surgeons. It did not follow that the milk of a cow was safe because its udder did not appear diseased.

Prof. STOCKMAN thought milk could not be affected if the udder was healthy, and all udder disease should be notified. General inoculation was hardly practicable, and dairymen would want impossible amounts for compensation. Inflammation cells in milk were suspicious.

Prof. O. WILLIAMS suggested that tuberculin should be scheduled as a poison to prevent fraud, and a small duty levied on sales to be used for compensation.

Prof. BANG said that in Denmark, under a law passed for the purpose, all cows with udder disease had been killed during the last three years. Milk from all suspected animals was sent to him for report, and his diagnosis of tubercle had been confirmed post mortem in ninety-nine per cent. In only fourteen per cent. of tubercul us cows with the udders unaffected did the milk cause disease when injected into guinea pigs. He recognized the value of outdoor treatment, but infection was the one cause, and a sound herd might be kept always indoors without becoming tuberculous.

Professors MCFADYEAN and CROOKSHANK both controverted Koch's statement, and other speakers pronounced it hasty or premature. One member, however, ventured to congratulate the milk-dealers on Dr. Koch's discovery, and said no people were more healthy than dairy farmers and milk vendors; but others did not support him, and in his reply Mr. Dollar said that French peasants who herded with their cows were very liable to phthisis, and in Queensland, where herds were constantly in the open air, tuberculosis was rife among them.

Third Day—Thursday, July 25.

Tuberculosis and the Milk Supply.—Mr. JAMES KING, Chief Veterinary Inspector of the City Corporation, opened the discussion. He said that tuberculosis very seriously affected the meat supply. So great were the losses entailed that farmers and purveyors had often forsaken the trade, and butchers were driven to the dead-meat market to escape the fear of confiscation. He, therefore, dealt more and more with foreign meat to the detriment of home supply. He might buy an ox for £30, and after slaughter tuberculosis might be found and the meat condemned. Mr. King had found the disease in some of the best cattle exhibited at shows when they were examined after slaughter, showing how prevalent is tuberculosis in even picked herds. He urged the necessity of legislation to prevent the home trade being quite destroyed. At present, he said, the purchase of oxen has become more of a gamble than a legitimate trade, and he asked how long this state of affairs is to last before some active steps are taken to reduce or stamp out cattle tuberculosis.

Sir GEORGE BROWN said great differences existed in the action of inspectors. He did not think many had read the recommendations of the Royal Commission.

Mr. BOWEN JONES said legislation could not be obtained except on the strongest evidence, and he was against including tuberculosis under the Contagious Diseases (Animals) Act. He brought forward some recommendations which, though supported by Mr. W. Cooper, were not voted on. Mr. Pearson and others advocated the minority report of the Royal Commission.

Mr. FIELD, M.P., said that tuberculosis had increased fifty per cent., the consumption of meat threefold. Many acting meat inspectors have no proper knowledge of their duties.

Mr. ANDERSON, of Glasgow, dwelt on the dangers of fraud in connection with compensation.

Prof. OWEN WILLIAMS would have inspectors appointed by central—not by local—authorities.

The Hon. W. P. REEVES, Agent-General for New Zealand, said tuberculosis was very common there, although the cattle lived so much in the open air. Every town of 2,000 inhabitants had its own slaughter-house, under government inspection. Owners of diseased beasts were paid half their value, and the flesh was destroyed.

Mr. HUNTING, editor of the *Veterinary Record*, said half the meat slaughtered escaped inspection altogether and thought compensation would relieve the butcher.

Fourth Day—Friday, July 26.

Legislation for the Control of Tuberculosis in Animals.—Prof. MCEACHRAN of Montreal read a paper opening the discussion on this subject, in which he offered the following as suggestive of the needed legislation:

1. Tuberculosis should be included in the list of contagious diseases. Tuberculous animals should consequently come under the provisions of the Contagious Diseases (Animals) Act, but the local authorities should have power to allow the sale and movement of such parts of the carcasses as were known not to carry contagion, such as hides, hoofs, horns, and hair, thus preventing unnecessary loss.

2. All foreign animals admitted for breeding or dairy purposes should be tested by the tuberculin test. Tuberculous animals should be prohibited from entering.

3. Tuberculin should be controlled, and none but qualified veterinarians be allowed to use it, and all reacting animals should be reported, marked, and quarantined.

4. All animals showing clinical symptoms of tuberculosis, especially disease of the udder, lungs, uterus, or bowels, should be killed at once, and all scrub and grade animals reacting should be killed within six months. Pure-bred cattle may be bred from under Bang's system, in quarantine for life.

5. All testing, of other than imported animals, should be by voluntary application for a test of the entire herd, and the expense should be borne by the State. A reaction of 2 per cent. should be understood to indicate tuberculosis, $1\frac{1}{2}$ per cent. should be regarded as suspicious. Suspicious animals should be quarantined and re-tested in three months, unless clinical symptoms developed, when they would be at once condemned; the Government should have the right to order a re-test when considered necessary.

6. Disinfection of premises should be ordered by special regulations, the carrying out of which would be superintended by Government officials.

THE MUSEUM AND THE DESCRIPTIVE CATALOGUE

The Organizing Council of the British Congress on Tuberculosis for the prevention of consumption acted wisely in making a museum a part of the programme, thereby affording opportunity for the careful study of the scientific aspect of the matter. This museum contained the concrete proofs of the scientific facts which form the basis of our knowledge of tuberculosis. Completeness was aimed at, and was attained, and it is no mere expression of words to say that there is not one scientific fact of the slightest material importance relating to tuberculosis which was not represented in this collection.

The museum was devised and arranged by Dr. Jobson Horne, who also compiled a catalogue fully descriptive of the contents and scheme of the museum. The catalogue, of about two hundred pages, contained a plan of the museum, five plates illustrating the pathological specimens, and a large number of statistical charts, maps, and diagrams. The catalogue was thus a compendium of facts relating to tuberculosis, which could profitably be kept for future reference.

The museum was divided into two main sections, which were further subdivided. The first section was the larger and was purely scientific. It illustrated in a systematic manner the bacteriology and pathology of tuberculosis. The first exhibit consisted of five tubes inoculated and exhibited by Prof. Koch, containing cultures of the tubercle bacilli which were the four hundred and thirty-fifth lineal descendants of the original bacilli isolated by him on August 15, 1881. Moeller and Rabinowitsch exhibited cultures of the acid-fast organisms bearing their names. Dr. Bulloch sent from the Bacteriological Laboratory of the London Hospital

an interesting exhibit dealing with the chemistry of the tubercle bacillus, and also of the bacillus phlei. Mr. Swithinbank exhibited a complete collection of cultural growths, and several varieties of tubercle acid-fast bacilli, organisms of pseudo-tuberculosis, and pathogenic streptothrices at different stages of growth. He also exhibited cultures of the bacillus tuberculosis which, after exposure to liquid air for periods varying from six hours to forty-two days, had lost neither vitality nor virulence. A culture by the same exhibitor made from a growth of actinomycosis after eight years of desiccation, demonstrated an extraordinary vitality.

The next division dealt with Experimental Tuberculosis, and in this were to be seen the preparations forming the basis of the opinion expressed by Professor Koch in his address, viz., that human tuberculosis differs from the bovine, and cannot be transmitted to cattle. By the side of these could be seen the results of the experiments conducted by Professor Sydney Martin for the Royal Commission in 1895, and these preparations afforded valuable opportunities for comparative study. The results attained at different periods from inoculating guinea pigs with tuberculosis were demonstrated by some excellent specimens by Mr. Shattock. Some colored drawings, illustrating the results of the late William Marcet's experiments in 1867, were of historical interest as well as of scientific importance.

The morbid anatomy of the subject was most fully dealt with. The systematic arrangement of the specimens, and the addition of preparations of normal organs for comparison and also of organs affected with diseases allied to or simulating tuberculosis afforded an unequaled opportunity for study. The morbid anatomy series contained some five hundred specimens which demonstrated every lesion tuberculosis has produced in the human body. Some of these specimens were of great historical interest. In the section dealing with tuberculosis of bone and organs of locomotion, there was exhibited a preparation of spinal caries from a patient under the care of Percival Pott, who first clearly described the condition in 1779. The suprarenal body from the first case in which bronzing of the skin was associated with disease of these organs was lent by Guy's Hospital, together with some similar preparations from patients under the care of Dr. Addison. Tuberculosis of the thoracic duct was represented by a most interesting little preparation, which the catalogue described as having been obtained from one of "the three cases of obstruction of the thoracic duct," dissected by Sir Astley Cooper, and described by him in 1708. To these cases Professor Benda, of Berlin, made reference in his paper on tuberculosis of the thoracic duct.

This long series of morbid anatomy specimens was almost entirely derived from the museums of the hospitals in London, which had been carefully searched by Dr. Horne for some months previously in order that the most unique and complete preparations might be brought together. Accompanying the descriptions of these in the catalogue were brief clinical histories which materially added to the value of the catalogue as a work of reference.

The histopathology of the subject was fully dealt with in the collection of upwards of sixty microscopic preparations. Following up this series was a collection of specimens illustrating the morbid anatomy of tuberculosis in animals and also macroscopic and microscopic preparations illustrating the comparative morbid anatomy. The exhibits illustrating recent research work included, among others, sections and preparations by Dr. Jobson Horne of the earlier stages of laryngeal tuberculosis, and the way in which the disease may become quiescent or arrested. Professor Benda sent a very complete collection of preparations showing tuberculosis of the valves of the heart, of the blood vessels, and of the thoracic duct.

The second section of the museum contained exhibits relating to the statistics, diagnosis, therapy, and prophylaxis of tuberculosis. Mr. Shirley Murphy exhibited charts and diagrams showing the effects of over-crowding. These were reproduced in the catalogue, and will repay a careful study. Sir Hugh Beevor exhibited charts illustrating the associations of phthisis in England. These were also reproduced in the catalogue, and brought out the facts that food supply and air supply are more closely related to phthisis than all other causes. But food seems more influential in the young, air supply in later life. Dr. Tatham sent some graphic charts showing the mortality from phthisis during the last forty years. Dr. Symons, Medical Officer of Bath, also sent some interesting charts dealing with tuberculosis in that city, and those from Dr. Kaye showed the history of and the death-rate from pulmonary tuberculosis in the West Riding.

The manufacture of tuberculin was demonstrated by photographs and models, and the processes were briefly described in the catalogue.

An architectural section containing drawings and plans of sanatoria and of hospitals, either already erected or in course of erection, had been arranged by Mr. Thomas W. Cutler.

(To be continued.)

BRITISH MEDICAL ASSOCIATION.

Sixty-ninth Annual Meeting, Held at Cheltenham, July 30, 31, August 1, 2, 1901.

(Continued from page 273.)

SECTION OF MEDICINE.

First Day—Wednesday, July 31.

The Value of Research in Medicine and Therapeutics.—Dr. E. T. Wilson of Cheltenham president of the section, delivered a brief introductory address with this title. He said that the scientific study of infective diseases has not only given improved diagnostic methods, but also has changed the therapy of such affections. Every disease gained to the infective class becomes preventable, and our treatment of it acquires a definite aim. He thought that from a scientific standpoint drugs have been unduly discredited. He deprecated the use of proprietary medicines of unknown formulæ and advocated the scientific investigation of new drugs and compounds in the laboratory and hospital.

Chronic Diseases of Joints Commonly Included in the Terms Chronic Rheumatism, Osteoarthritis, and Rheumatic Gout.—Dr. A. E. Garrod of London in opening this discussion, said that the subject of joint diseases must be considered *de novo*, as current views of their pathology had gone through many changes, from purely articular through the stage of articular with visceral complications, up to the view that they were only outward manifestations of a constitutional diathesis or disease, an infective fever with arthritis. Were the cases grouped under the heading of rheumatoid, or osteoarthritis, really examples of a single malady or not? Their clinical and pathological pictures did not agree. At least two main groups called for special mention: (1) the fusiform type in young and middle-aged women with great muscular atrophy, and very little evidence in the early stages of bony changes, but with a good deal of constitutional disturbance; and (2) a nodular type occurring in later life, with no constitutional change, but with much evidence of bony destruction or alteration. He believed the two groups were specifically distinct, and not stages of the same malady. Did these two groups have any relationship with bone rheumatism, on the one hand, or with gout, on the other? Taking the fusiform group first, he gave reasons for holding that even these had no real relationship to true rheumatism. On the other hand, he said it was far less easy to assert that bone rheumatism played no part at all in the causation

of rheumatoid arthritis. It might be doubted whether the relationship would ever be settled by mere clinical observation, but possibly bacteriological evidence of a conclusive character in one direction or the other might soon be forthcoming.

On the possible relationship of the nodular type of osteoarthritis to gout, the problem was somewhat different. In most cases there was no evidence of a gouty origin of the changes, and he regarded rheumatic gout as a hopeless term.

In the cases of joint trouble occurring in children, which so closely resembled the fusiform type of rheumatoid arthritis in adults, the enlargement of the spleen and lymphatic glands so commonly observed lent some support to a bacterial origin of the malady; but he thought it advisable to maintain an expectant attitude on the question till further bacteriological research afforded a surer basis for the erection of theories as to their pathology. In regard to treatment of these chronic joint diseases, he advocated (1) the removal of all debilitating influences, such as profuse menorrhagia, dyspepsia, etc., and especially of unhealthy states of the gums; (2) a generous dietary; (3) some drugs such as cod-liver oil, iron, and arsenic; and (4) massage to the affected muscles and especially the douche massage.

Dr. William Osler of Baltimore agreed that the problems must be faced without prejudice from inherited views. Confining his remarks to arthritis deformans, whether in children or adults, he thought there were two groups: (1) An infective group, comprising the fusiform type in adults and the variety in children with enlarged glands; (2) a dystrophic group. The former resembled true rheumatic fever very closely, and the diagnosis could not be made for a long time after the acute onset. The latter group included the so-called spondylitis deformans when it affected the spine, and the bulk of the old-age cases without much or any constitutional disturbance.

Mr. Wm. Armstrong of Baxton thought that while the local joint changes in the diseases in question were practically identical, the exciting causes were very different, but he reduced them to two, viz., (1) bacterial invasion, and (2) neuropathic changes. He quoted cases in support of the neural hypothesis: (1) A young woman who rapidly recovered from two attacks of acute rheumatism, but with the third had nerve strain, and then was crippled; (2) a man with gout who had, after several attacks with recovery, an attack combined with business worry, which then took a crippling shape; (3) a case of osteoarthritis, with influenza as the bad element; (4) an arthritis following duodenal autointoxication. Lowered health was the factor common to them all, and which he thought influenced the joint affection for evil. Treatment should, therefore, be directed (1) to the basic cause, (2) to eliminate reflex irritation, and (3) to build up the health. He had found the prolonged administration of arsenic and bromides distinctly useful.

Dr. A. P. Luff of London thought that osteoarthritis was often a dystrophic sequela of rheumatism. He gave a sketch of his term osteoarthritis, and inclined to the microbic theory of origin rather than to the neuropathic. He thought the monarthritic form a distinct disease. He advocated a generous diet for treatment, and had seen good results from radiant heat and some of the guaiacol preparations.

Dr. W. P. Herringham of London adverted to the difficulty of diagnosis between acute rheumatism and osteoarthritis. The diagnosis might be summed up as true rheumatism having permanent cardiac lesions and transitory joint trouble, and osteoarthritis having temporary cardiac trouble, with permanent joint lesions. He argued for the identity of the disease known as rheumatoid arthritis, although he granted that in old people the disease was osteal rather than synovial, that in children there was fever, but not in old persons, also that in them there were glandular affections. The difference in type, he attributed not to the pathological process, but to the difference in tissue proclivities at the different ages. For example, epithelial inflammations were characteristic of young life, and fibrous degenerations of late life. These tendencies might be enough to account for the differences in joint changes without assuming the existence of separate diseases. At any rate he appealed against the subdivision of the disease rheumatoid arthritis until more evidence was available. In regard to treatment he especially recommended the winter climate of the Grand Canary Island.

Dr. Hawthorne of London could not recognize any three distinct groups of chronic joint diseases or even two, the types merged into each other. It was debatable whether the poison of acute rheumatism was the cause of chronic joint affections. Joint changes indistinguishable from those known as rheumatoid arthritis sometimes followed attacks of subacute rheumatism, and these deformities were sometimes associated with endocarditic changes and fibrous nodules. He advocated the disuse of terms involving theoretical considerations.

Dr. W. Calwell of Belfast remarked on the frequency of this group of diseases in the lower animals. Arthritis might be caused by several poisons, although structural changes might vary with each. He referred to the etiological bearing of defective hygiene, uncleanliness, with cold and damp. Defective clothing and water supply had also a causal significance. He considered early morning bathing an important preventative.

Dr. Eliza Dunbar of Cheltenham believed that rheumatoid arthritis had a microbic organ, but considered that overstrain in neurotic girls was an active contributing cause, and that the prevention of the disease in girls was possible.

Dr. E. J. Cave of Bath confined himself to the question of etiology. Various infective agents might produce identical anatomical changes; and the same infection might give rise to different anatomical changes. He described a case in which a septic infection was definitely the cause of a typical rheumatoid arthritis. It was necessary especially to investigate the earlier stages of the condition. Certain persons had probably a special proclivity to joint affections from any cause. In treatment he hoped for good effects from serum-therapy.

Dr Samuel West of London considered the etiological factors the only satisfactory basis for discussion. From his own experience, he held that if in early cases of rheumatoid arthritis a search were made for some source of general infection, and if this were removed cure of the joint condition would follow. It was probable that the joint changes resulted from the absorption of the toxins of several bacteria.

Dr Saundby of Birmingham also thought that the etiological basis was the most important point to establish. Much was still unknown, but it was known that certain forms of arthritis followed certain infections.

Dr. Sarat K. Mullick of London argued in favor of the neural theory of the origin of the disease, particularly referring to the associated trophic skin changes and to exaggeration of the deep reflexes.

Dr. Preston King of Bath maintained that rheumatoid arthritis was a general disease of the system, of which the joint changes were only a part.

Escape of Cerebrospinal Fluid from the Nose.—Dr Watson Williams of Bristol in conjunction with Dr Stocker of Clevedon, showed and described the case of a patient who suffered from a persistent escape of cerebrospinal fluid from the nose.

Pneumococcic Arthritis.—Dr Nathan Raw of Liverpool presented a communication based on seven cases of pneumococcic arthritis occurring in the course of 700 cases of lobar pneumonia. The pus in the joints was sweet smelling and contained no other microorganism.

Second Day—Thursday, August 1

Peripheral Neuritis in Beer Drinkers.—Dr ERNEST S. REYNOLDS of Manchester opened a discussion on "Peripheral Neuritis in Beer Drinkers, its Precise Causation and Diagnosis." According to his experience, alcoholic paralysis occurred almost invariably in those who either drank beer alone or beer in combination with spirits; and that pure spirit drinkers suffered more from delirium, mania, and gastric and hepatic disorders. A description of the epidemic of peripheral neuritis in Manchester and district, the characters of which are now well known, was described, and the steps leading to the incrimination of arsenic in the beer drunk were detailed. This epidemic had not proved that true alcoholic neuritis did not exist. There were three possibilities: (1) That the neuritis was entirely caused by the alcohol in the beer, and that the skin lesions and irritation of the mucous membranes were due to arsenic; (2) that all cases of so-called alcoholic neuritis were really due to arsenic; and (3) that, although either was able to produce neuritis alone, the cases in the Manchester epidemic were due to their combined action. The first possibility was dismissed, in view of the recognized occurrence of arsenical neuritis. In favor of the second possibility was that although alcohol was consumed in large quantities in Scotland, Ireland, and London, yet alcoholic neuritis was rare, certainly rarer than it had been for years in the Manchester district. The recent epidemic had been shown to be due to arsenic, and he had seen no case of neuritis in a person who had not drunk arsenicated beer. During the seven months that the Manchester district had been free from arsenicated beer no cases of neuritis had occurred in his experience which were not relics of the epidemic. It was suggested that even spirits and wines might be frequently contaminated with arsenic. Suphuric acid was said to be added to brandy and gin for trade purposes, and even in the case of whiskey crude sulphuric acid was sometimes used to cleanse the stills. In answer to the question, if arsenic had been the real cause in the past of alcoholic neuritis why had not the characteristic skin eruptions been observed, it was suggested that minute doses of arsenic taken for a long time might be sufficient to produce neuritis, and insufficient to produce skin changes or those in the alimentary tract, for arsenic was a cumulative poison; on the other hand, either that skin changes that were present were not noticed or that they were attributed to other causes than arsenic—for example, to the effect of vermin; and it was to be remembered that pigmentation did not occur in fair people. In regard to the third possibility—the combined action of arsenic and alcohol in producing so-called alcoholic paralysis—he was convinced that, considering the amount of pure alcoholic beverages consumed in the world, true alcoholic neuritis was one of the rarest diseases known, and that large numbers of the cases recorded as such were really due to this combination. Arsenic in an alcoholic subject was much more virulent than when taken alone. In every case of alcoholic neuritis, concomitant symptoms should be looked for, and the urine and epidermal structure should be examined for arsenic. The differential diagnosis of the form of neuritis seen in the epidemic from that seen in beriberi was discussed, and it was suggested that some of the supposed outbreaks might be due to chronic arsenical poisoning.

Professor DIXON MANN of Manchester in describing the characteristic symptoms in the Manchester epidemic, thought that the excessive muscular tenderness was probably due to the fact that the neuritis was more acute than that usually ascribed to alcohol alone. He had found no evidence to support the view, as was suggested, to meet the difficulty arising from the smallness of the amount of arsenic, as compared with the magnitude of the results, that the arsenic existed in organic combination. The Royal Commission had stated that the amount ranged from one and one-half grains to three grains per gallon, and he had all along expressed the opinion that more was present than the published analyses stated. He had been greatly struck with the amount of arsenic that was stored up in the keratin structures of the skin, indicating a strong affinity between them. Neurokeratin was a large constituent of the white matter of the central nervous system, and his analyses had shown that the white matter contained much more arsenic, weight for weight, than the grey. In regard to the precise manner in which arsenic produced the neuritis, it was probable that it acted on the nerve centres as well as the peripheral nerves. The ultimate result of the action of arsenic was fatty change in the nerves, and this he was inclined to ascribe to an action similar to that believed by Hott to belong to phosphorus, namely, that it interfered with the power of the protoplasm to take up and store oxygen probably from both a lowered vitality of the cells and a direct chemical action on the proptoplasm.

Dr. A. P. LUFF of London believed that alcoholic and arsenical neuritis were distinct conditions. In alcoholic neuritis there was no excessive muscular tenderness, and no pigmentation or other characteristic change in the skin. If all cases of alcoholic neuritis had been due to arsenic it was very unlikely that the toxicological examinations that had been made in many cases would not have revealed it.

Dr. KELYNACK of Manchester gave the results of an investigation into the frequency of peripheral neuritis in the Manchester Royal Infirmary, as compared with hospitals in Cambridge, Dundee, Belfast, and London, showing that much of the so-called alcoholic paralysis met with in Manchester of late years was due to arsenicated beer. The conditions of the introduction of the arsenic into the system during the epidemic led to an increased rate of absorption, an exceptional accumulation in the body, and a retarded elimination. The alcohol and other ingredients of the alcoholic beverages greatly accentuated the toxic effect of the arsenic.

Dr. OSLER of Baltimore had never seen a case of alcoholic neuritis in a person who had taken beer alone, but he did not meet with more than two or three cases in a year. He had never observed in these cases pigmentation, keratosis, bullous lesions, or herpes, although he had been for many years well acquainted with the skin lesions due to arsenic. Hyperæsthesia of the skin and muscles varied greatly in different forms of neuritis; he had seen it in most intense forms in post-typhoid neuritis.

Dr NATHAN RAW of Liverpool had had under his care two hundred and twelve cases of the epidemic neuritis, which might be divided into acute and chronic—the acute being due to a sudden increase in the amount of arsenic in the beer occurring late in the epidemic, reaching one and a half grains to the gallon, and the chronic to the ingestion of small doses of arsenic for a term of months. The skin lesions were characteristic of the epidemic. The explanation of the whole question was the combined effect of arsenic and alcohol. Since the epidemic had ceased, and arsenic had disappeared from the beer, the number of cases of alcoholic neuritis remained much the same as before. He believed peripheral neuritis could be produced by alcohol alone, either in beer, in whiskey, or in other spirit. In arsenical cases, the sensory symptoms predominated, both the motor and sensory changes passed off more readily and completely than in the alcoholic cases, and relapse might occur in the arsenical cases, suggesting that arsenic was cumulative.

Dr WALDO of Bristol had seen extreme muscular tenderness in cases of alcoholic neuritis, and arsenic given alone, medicinally, rarely produced neuritis.

Dr. POPE of Leicester remarked that all the cases he had seen in Leicester were in persons who had drunk

beer from one brewery that had used the contaminated glucose from Liverpool. He had difficulty in believing that alcohol alone could produce neuritis, seeing that many persons drank enormous amounts of spirits without developing it.

Mr. ORMROD of Workington had seen skin eruptions in several cases, but no marked pigmentation.

Dr. CATON of Liverpool had traced cases of neuritis occurring in beer drinkers to contamination with lead.

Sir WILLIAM GAIRDNER of Glasgow had seen no case of peripheral alcoholic paralysis until 1884, when the late Dr. Ross had shown him six at one time in the Royal Infirmary in Manchester, although it had been his duty, as a teacher of medicine in Glasgow, to study types of disease. He had remarked to Dr. Ross on the rarity of the disease in Scotland, considering the amount of whiskey drunk. Since then he had been carefully on the lookout for the disease both in hospital and in private and he had not met with even ten cases. This, he believed, argued some other localizing cause than alcohol, and no doubt in the recent epidemic that cause was arsenic.

Treatment of Acute Rheumatic Endocarditis.—Dr. CATON of Liverpool then read a paper on the arrest of the acute endocarditis occurring in the course of acute rheumatism by means of rest, the application of small blisters to the chest, and the administration of sodium iodide. If no special treatment were devoted to the heart-complications of rheumatism and if, immediately after its subsidence, patients returned to ordinary life, permanent organic cardiac disease would probably develop. But in all cases, and especially those in children, if commencing valvulitis were detected and this method of treatment adopted, permanent crippling of the heart would be avoided.

Dr. OSLER had not been able to determine in his own practice whether Dr. Caton's plan of treatment was followed by good effects or not. The permanent heart lesions which were serious were not due to the vegetations, but to the sclerotic changes in the valves which were set up.

Dr. HAWTHORNE of London remarked that it was the insidious forms of rheumatism occurring in childhood that were particularly dangerous. Early and complete rest was the best means of preventing endocarditis.

Professor CLIFFORD ALLBUTT of Cambridge stated that in his experience well marked physical signs of a previous endocarditis, in a substantial minority of cases, wholly disappeared. Not only should all means be employed to reduce blood-pressure in these cases, but blood-mass should also be kept down by a reasonable limitation of the fluids ingested.

Sir WILLIAM GAIRDNER of Glasgow emphasized the importance of absolute rest for persons who had had acute or subacute rheumatism, not only during the earlier stages but after the temperature had fallen and all joint swelling and pains had ceased.

Dr. WILLIAM EWART of London thought that the good effect of the treatment described depended more on reducing the rate of development of the valvular lesions than in curing them.

Sir WILLIAM BROADBENT of London deprecated the stereotyping of any plan of treatment. Rest and reduction of the volume of the blood were of the utmost importance. In his experience, too, murmurs sometimes disappeared after an interval of years. Murmurs might be present even when the heart was functionally efficient. It was of great importance to give salicylates in large doses in the early stages of acute rheumatism, during the first forty-eight hours, and this he thought was effective in preventing endocarditis.

Dr. SAMUEL WEST of London drew attention to the unreliability of statistics in regard to acute rheumatism. It was possible for cardiac murmurs to disappear in the presence of organic valvular disease, the existence of which was subsequently proved by post-mortem examination. The importance of rest could not be exaggerated. It was possible to demonstrate by percussion a dilatation of the heart following on a patient leaving the recumbent position.

Third Day—Friday, August 2.

Bacteriology of Fetid and Gangrenous Suppuration.—Dr. EDWARD RIST of Paris read an important paper on this subject, describing some new methods and new results. The particular method he referred to was one invented by Dr. Veillon of Paris, by which anaerobic germs could be easily cultivated in agar tubes. He had made investigations with this method on the bacteria of mastoiditis and otitis media. The cases described of mastoiditis caused by streptococcus or pneumococcus alone, certainly existed, but they were very rare, the discharge was not fetid, and the form of the disease was a mild one. In the greater majority of cases, the mastoiditis was preceded by chronic, fetid otorrhœa, and was itself of a very fetid character. These cases were generally severe, and liable to be complicated by other fetid and gangrenous suppurations. They were caused by anaerobic germs, which were able to destroy the tissues by a process of putrefaction. He had found the same anaerobic germs in the disseminated metastatic gangrene of the lungs caused by otitic septicæmia. Guillemot had made a special study of pulmonary gangrene in general, and had shown that it was always caused by anaerobic germs, and that the process of gangrene was a real process of putrefaction. Dr. Rist had investigated several cases of putrid pleurisy connected with either cortical gangrene of the lungs, bronchial dilatation, or abscess of the liver, and had always found them to be caused by anaerobic germs. In one case, after pleurotomy, the infection penetrated through the cutaneous wound into the connective tissue between the dorsal muscles, and caused a gangrenous and gaseous phlegmon which extended with alarming rapidity; the discharge contained the same anaerobic germs which had already caused the pleurisy.

Dr. Veillon, with Dr. Zube, had been able to show that in nineteen cases of appendicitis out of twenty-one the pus was full of anaerobic germs, sometimes, but not always, associated with some rare and comparatively harmless streptococci or coli bacilli. The same had been shown by Dr. Cotret in periurethral suppuration, by Dr. Hallé in some cases of uterine inflammatory processes, and by Dr. Teissier in intestinal diseases in infants. A critical review of many observations published by several authors had convinced him that cases believed to be of typical streptococcic otitic septicæmia, for instance, were polymicrobic infections, in which the anaerobic germs had been overlooked.

In many cases there were only anaerobic germs in the pus. He had seen a case of mastoiditis, and another one of putrid pleurisy where not a single colony grew on ordinary agar plates, whilst anaerobic germs grew abundantly in agar deprived of oxygen. He had studied a case of fetid pyosalpinx, where the ordinary plates remained altogether sterile; the cultivation in anaerobic tubes allowed him to isolate six anaerobic species, among which two different streptococci, which, in stained preparations, would certainly have been mistaken for streptococcus pyogenes. He therefore asserted, as a result of the researches he had described, that anaerobic germs were the specific agents in fetid suppurations and active gangrenous processes.

Indigouria.—Drs. A. MCPHEDRAN and GOLDIE of Toronto reported a case of indigouria in a patient who had dyspepsia due to bolting his food. The urine contained a mere trace only of indican.

Treatment of Intestinal Diseases.—Dr. J. A. RIVIÈRE of Paris read a paper on the abortive and curative treatment of acute intestinal diseases, particularly enteric fever and appendicitis, with calomel, conjoined with bicarbonate of sodium and quinine, and followed by the

administration of water by the mouth and warm applications to the abdomen. The principle on which the employment of calomel was based was that it stimulated the secretion of bile, which exerted its antiseptic action on the microbes in the intestinal tract causing the particular disease, and to a less extent that it stimulated the excretory functions of the liver.

Electricity in the Treatment of Pulmonary Tuberculosis.—Mr. CHISHOLM WILLIAMS of London described his results in the treatment of pulmonary tuberculosis by means of electrical currents of high frequency and high potential. He referred to forty-three cases so treated, all being of a severe type. At first, after each application, the temperature rose, but each successive rise was less, and when no rise followed, arrest of the disease had occurred. Cough was lessened. Expectoration at first was increased, and sometimes became rusty, but its offensiveness lessened and eventually became almost absent. The number of the bacilli first increased, then decreased. Weight was put on, and all the symptoms were coincidentally alleviated. The average term of treatment was about three months.

Treatment of Cardiovascular Diseases.—Dr. H. J. CAMPBELL of Bradford communicated a paper on the treatment of cardio-arterial disease. After describing the commoner forms of the disease, he stated his plan of treatment as directed to the reassertion of balance between the force of the heart and the resistance to the blood-flow through the vessels, by influencing either the heart or the vessels. Each case had to be treated on its special indications, with this end in view. He had found the sphygmometer of Hill and Barnard of the greatest value in his observations. In the cases with but slight vascular disease, but with a hypertrophied and failing heart, in addition to enjoining suitable hygienic measures, he gave nitroglycerin, a dry diet, and aperients. In the second group of cases, with primary vascular disease and secondary cardiac hypertrophy, he gave small doses of strophanthus, with potassium iodide, together with graduated exercises. If sclerosis of the kidney were present, he gave milk diet and sodium iodide.

Diagnostic Value of Tubercle Bacilli in Phthisis.—Dr. J. A. CHOWRY-MUTHU of St. Lawrence, Isle of Wight, read a paper on this subject. The number of bacilli present was of much less importance than their virulence. The symptoms and signs usually ascribed to consumption did not necessarily mean the presence of tubercle; other microbes might produce similar phenomena. But the absence of tubercle bacilli from the sputum did not negative the presence of tuberculosis, although their occurrence was certain evidence of its presence.

Drug Idiosyncrasy.—Mr. C. GRIFFITH WILKIN of Yeovil narrated a case of rheumatic endocarditis in which there was excessive intolerance to morphine, nux vomica, and quinine.

Zomotherapy of Phthisis. Dr. FORBES ROSS of London read a paper on the value of a dietary of meat albumin in the treatment of tuberculosis. Milk albumin did not, and myosin did, produce a stable tissue nutrition. It was suggested that this might be due to the fact that myosin was a fixed albumin, while milk albumin was an excreted albumin. But it was stated that it might advantageously be mixed with milk, and was in no way contrary to the simultaneous employment of other approved methods of treatment.

Mucin in Intestinal Diseases. Mr. W. STUART LOW of London read a paper describing the good effects of the administration of mucin by the mouth, combined with bicarbonate of sodium, for conditions of irritability, desiccation, and ulceration of the gastro-intestinal tract.

SECTION OF SURGERY.

Third Day. Friday, August 2.

Injuries to Joints.—Mr. HOWARD MARSH opened a discussion on "Injuries to Joints with Special Reference to their Immediate and Remote Treatment by Massage and Movement." He thought that massage should always be employed under the direction of skilled surgical advice, in his experience unfortunate accidents sometimes had followed its inconsiderate use. Massage increases the circulation through a part, removes exudation, and acts as a stimulus through the nervous system. It acts also as a sedative in relieving muscular spasm, and promotes the absorption of recent adhesions. Movement might be used in three ways. In the first place, in joints structurally normal but hampered by adhesions this would be done under an anæsthetic; secondly, subsequent ordinary passive movement; and thirdly, movements against resistance. This treatment was specially applicable in sprains and contusions of previously healthy joints. A skiagram was always useful. Complications that might be overlooked were fractures, subluxation, rupture of muscles, or displacement of tendons. The latter was, in his experience, rare. In recent dislocations he was in the habit of carrying out passive movement early, after a few days, instead of using fixation apparatus. It is important to decide whether an injury is inside or outside a joint, if the bones could be moved within a limited range easily and in a normal way the injury was in all probability mainly to structures outside; this he looked upon as a valuable diagnostic sign. In long-standing cases the question must be decided as to what has been the cause of the delayed recovery. Complications of injuries that must always be kept in mind were sarcoma and hæmophilia. After forcible movement under an anæsthetic massage should be carried out daily for some three weeks.

Mr. WHITELOCKE confined his remarks to the treatment of recent injuries to joints in young adults. An anæsthetic should be used to make an exact diagnosis. He then used elastic pressure, and within twelve hours after the injury he commenced passive movement, and continued it daily along with massage. About the tenth day he allowed active movement, and within three weeks he had always found that these injuries were sufficiently recovered from to allow of the resumption of athletics. He deprecated the use of all rigid apparatus.

Mr. F. BURGHARD had obtained good results in cases of shoulder dislocation from massage and the discarding of all fixed apparatus. He was in the habit of repeating passive movement under gas once a week.

Dr. WARD COUSINS always used an antiseptic bath in case of subcutaneous injuries near joints. He had found the hot-air bath of much service in cases complicated by rheumatism. He applied massage in the first instance to the surrounding muscles and tendons. He agreed with the recommendation of early movement and massage.

Mr. BARLING agreed with Mr. Whitelocke in his use of elastic pressure, but had not found recovery in cases such as those described by the latter so rapid as three weeks. He had found that most of the subjects of these injuries were out of condition in regard to their muscular system, and therefore did not allow active exercise early. In Colles' fracture he discarded the use of splints unless the deformity was great.

Mr. PAUL BUSH laid emphasis on the fact that in forcible movement under an anæsthetic the joints should be carried through their extreme range of motion.

Mr. RUTHERFORD MORRISON thought that care should be taken to distinguish injuries to the joints themselves from injuries to their surroundings. In cases of true joint injury he did not recommend the universal use of massage. In cases of displaced semilunar cartilage and fractured patella he always insisted on a considerable period of rest after operation.

Mr. Marsh, in replying, said he agreed with Mr. Whitelocke as to the value of elastic supports applied by means

of cotton wool and Martin's bandage immediately after a sprain. The effusion which would otherwise occur from the ruptured or temporarily paralyzed blood-vessels would be to a large extent prevented and very little swelling would take place. He employed passive movements very early—within twenty-four hours. After suture of the patella or the removal of a semilunar cartilage, as soon as the wound was healed—that is, within seven or eight days—the splints were removed and passive movements were begun and carefully increased while massage of the muscles was daily employed. After suture of the patella the patient was allowed to walk, wearing a rigid apparatus, within a month of the operation, while both morning and evening he was directed to practise gentle movements, without bearing any weight on the limb. The speaker agreed with Mr. Barling as to the dependence of the joints on the surrounding muscles for security and protection. When muscles were weak any violent exertion was very likely to lead to joint damage. He further entirely agreed with his views as to the treatment of many examples of Colles' fracture without splints. The deformity (even in non-impacted fracture) was often but little marked and was not material. The loss of power and the stiffness often remaining after this fracture were not due to the mere deformity of the bones but to the fact that the tendons and other soft parts had become fixed by adhesions, which had formed while the limb was immobilized for three weeks, or even longer, as the custom of some was, on splints. He had seen several cases in which, although there was distinct, even marked deformity, the use of the hand was scarcely at all interfered with.

Treatment of Congenital Dislocation of the Hip.—Mr. F. F. BURGHARD of London read a paper on this subject. He first gave a brief account of the anatomical peculiarities present. He had obtained no satisfactory results from apparatus. He described Lorenz's bloodless method, and remarked that only in a few cases was there true reposition, as the head usually left the acetabulum later. He had had experience of twenty cases. In two he had used the Paci method with disappointment, as regards the final result. In nine cases he had carried out Lorenz's bloodless method. In one the result was perfect, in five fair, and in two failure. He had five times performed Lane's operation, but now believed that the method rested on a misapprehension. In five other cases he had performed a modified Lorenz's method of open operation, with good results.

In children under two he recommended only active and passive movements. Between the ages of two and five he recommended Lorenz's bloodless method under the control of the *x*-rays. About the age of five he believed the open operation of Lorenz gave the best results. After the age of seven he did not advise operation.

Mr. HOWARD MARSH thought that those cases alone required operation in which there was much displacement upward and backward, and where there was a sliding condition of the head.

Reducibility of Long-standing Dislocations.—Dr. E. W. DUNBAR read notes of two cases of old standing dislocation successfully rectified. One was a partial dislocation of the right hip joint of five years' standing. The other was a case of partial dislocation of the right sacro-iliac joint, which had existed for six years. Both were illustrated by skiagrams. Both were reduced under anæsthesia.

Mr. BUCKELL thought that the ease in reduction was due to the fact that the dislocation was partial in each case.

Hydatids of the Pleura.—Mr. WHITELOCKE read notes of the case of a young woman who had been treated by thoracic section for hydatid of the right pleura. The mother cyst was not removed at first, but was thoroughly scraped. A sinus persisted for ten months when the mother cyst came away; it then closed.

Mr. MICHIE of Adelaide related a similar case.

Dr. T. RANKIN related a case of amputation of the right leg at the knee for senile gangrene in a man aged seventy-two.

Mr. CHICKEN showed a collection of sixty-seven loose bodies removed by operation from a knee joint.

(To be continued.)

The Bacteriology of Cystitis, Pyelitis, and Pyelonephritis in Women.—Thomas R. Brown concludes that (1) the direct cause of the infection of the urinary tract in women is the invasion and multiplication of some form of microorganism; (2) the commonest cause of these infections is the B. coli communis, which a consideration of the cases of acute cystitis definitely proves can and does in a large number of cases set up a true infection without the aid of any other microorganism; (3) marked variations are seen in the virulence of this microorganism and in its pyogenic properties; (4) other microorganisms frequently found are the tubercle bacillus, various staphylococci, and the B. proteus vulgaris; while numerous other varieties have been less frequently met with, as the B. pyocyaneus and the typhoid bacillus; (5) the proportion of cases of infection due to the B. coli communis is greater in women than in men, probably because of the close proximity of the female urethra to the anus; (6) besides the microorganisms, other factors are in most cases necessarily essential to the development of a cystitis; the chief being anæmia, malnutrition, trauma of and pressure upon the bladder, congestion of the bladder, and retention of urine; (7) in cystitis the chief mode of infection is by the urethra, although one must also consider the possibilities of a descending ureteral infection from an infected kidney, pyogenic metastasis by means of the blood and lymph currents, and direct transmission of the microorganisms from the intestinal tract, or from some adjacent focus of infection; (8) in pyelitis and pyelonephritis the usual modes of infection are along the ureter from an infected bladder, and by means of the blood and lymph currents; (9) in the great majority of cases of cystitis, both acute and chronic, and in the majority of cases of pyelitis and pyelonephritis, the urine is acid; (10) irritation caused by ammoniacal urine is apparently sufficient to render the bladder susceptible to infection without the aid of any other etiological factors; (11) in infections of the kidney due to a urea-decomposing microorganism, a stone is very likely to be present if the case is at all chronic; (12) certain conditions exist which present most of the symptoms of cystitis but no infection, the most difficult of which to diagnose is probably urinary hyperacidity of neuropathic origin; (13) the diagnosis of renal infections can be made with absolute certainty only by ureteral catheterization, but a probable differentiation between renal and vesical infections can be made by a careful study of the urine alone; (14) tuberculous infections of the urinary tract frequently occur with no other demonstrable tuberculous lesion elsewhere in the body.—*Johns Hopkins Hospital Reports.*

What are the Most Efficient Remedies for Shock, Syncope, or Temporary Exhaustion; and How should they be Used?—N. S. Davis says that in all cases of profound shock and syncope the most important thing is to increase the force and depth of respiration in order to get more oxygen into the body. The patient should be kept in the horizontal position, cold water dashed on the face, and compresses of hot and cold water alternately applied to the dorsal and cardiac regions. As soon as the patient can swallow a little cold water should be given, and then a cup of meat broth without pepper. Meat broth may be given in enema, if necessary, as may also decinormal salt solution. Valerian and assafœtida will allay restlessness. Opiates and anæsthetics should be avoided. Well-salted meat broth will increase the saline elements of the blood. Stimulants, especially alcohol, are apt to do more harm than good. The author considers it folly to use alcohol, ether, strychnine, digitalis, etc., in the same patient, as is often done, for this group of remedies is easily divisible into two classes, the respective effects of which, are antagonistic. All exert their most prominent influence on the cerebrospinal nerve structures, including the centres of respiration and circulation. But while the strychnine and digitalis increase the cerebrospinal activity and promote respiratory, cardiac, and vasomotor efficiency, all authorities agree that the alcohol and ether directly diminish cerebrospinal sensibility and action, including the centres of respiration and circulation, thereby causing relaxation of the peripheral capillaries and arterioles, less depth of respiration, and less systolic force of the heart. Pushed to full or toxic doses strychnine so strongly excites the nerve centres as to produce rigid muscular contraction with acute sensibility, while alcohol in large doses relaxes every voluntary muscle in the body, enfeebles both respiration and circulation, and renders the patient insensible. It would be difficult to find two remedies in the materia medica more directly antagonistic in their effects on the living body than alcohol and strychnine. Yet they are both persistently called stimulants and both given not only in cases of shock and syncope, but also in a large majority of cases of typhoid fever, diphtheria, pneumonia, etc.—*Illinois Medical Journal.*

Seasonal Variations in Growth of Boys between the Ages of Seven and Fourteen Years.—The observations recorded below were made by F. W. Hitchings and G. W. Fitz, at one of the Boston institutions. All the children were weighed, stripped, once a week, and heights were measured every three months, except in the third quarter, which occurred in August. Twenty out of the thirty boys in the home remained throughout the year, and these only are considered. The results of the study are as follows: (1) Variations in weight amounting in some cases to as much as five pounds were observed in most of the boys from week to week. These variations were so numerous and so marked as to suggest that any single test of an individual is liable to a plus or minus error of several pounds, and that successive weighings are necessary for accuracy. (2) Over ninety per cent. of the total increase in weight occurred during the period from June to December. (3) During the period from January to June the weight fluctuated without definite gain or loss, constituting a period of minimum growth. This seemed to be made up of shorter periods of gain and loss, which practically neutralized each other and were more or less variable in their occurrence and in their range in different individuals. (4) The weight fluctuations were much more marked during the period of minimum growth in weight than during the period of maximum growth. This seemed to indicate that there was less resistance to external influences during this time, and that on the whole the vitality of the child was at a lower level. (5) A preliminary study of the weather conditions in connection with these curves of growth showed that rainfall, temperature, and barometric pressure had slight, if any, influence. Humidity, on the other hand, seems to have had some influence during the period of minimum growth. (6) The general form of the curve of growth in weight was found common to all the individuals studied (20), covering the ages from seven to fourteen. The larger minor fluctuations were also found to be common to the majority of the boys, suggesting that the causes were general rather than individual, and that growth throughout this age period has the same general seasonal variation. (7) Growth in height in the majority of cases showed either a continuous increase at the same rate throughout the year or more rapid growth during the period of most rapid increase in weight.—*Journal of the Boston Society of Medical Science.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 17, 1901:

METASTATIC CHORIOIDITIS OCCURRING IN THE COURSE OF PNEUMONIA, DUE TO GRIPPE. BASED ON A STUDY OF SIX CASES WITH TWO AUTOPSIES.*

BY CHARLES STEDMAN BULL, A.M., M.D.,
NEW YORK.

THE few remarks accompanying the reports of these six cases, are confined to the subject of metastatic ophthalmia, occurring in the course of pneumonia and endocarditis, due to influenza, and have no application to other forms of metastatic inflammation in the eye, due to the puerperal state, or to general septic poisoning, or to the epidemic form of cerebrospinal meningitis.

The diplococcus is known to be the cause of epidemic cerebrospinal meningitis, and it is probably the cause of the inflammation of the uveal tract so often met with in this disease. These cases do not end in panophthalmitis, and I believe that no accurate report has ever been published of any microscopical examination of such eyes.

Metastatic ophthalmia was first observed in cases of puerperal fever. It was subsequently met with in other forms of septic fever, and was described as pyæmic or phlebitic ophthalmia. In 1856, Virchow discovered in a metastatic panophthalmitis capillary emboli in both retina and chorioid. This discovery established the fact that purulent chorioiditis does occur as a metastatic affection, and experience has since satisfactorily proved that both eyes may be attacked, one shortly after the other. The disease is always due to septic infection, and microorganisms can nearly always be found, when the opportunity occurs to search for them. The lesion in the eye is often closely dependent upon a general septic condition of the system, which is sometimes fatal, and which is always of such gravity as to overshadow the local condition. The microorganisms which have been found in such cases are the staphylococcus albus and aureus, the streptococcus pyogenes, and the pneumococcus. Bacterial thrombi have been demonstrated in the vessels of the uveal tract, retina, conjunctiva, ocular muscles, and orbital tissue.

We know that in very acute sepsis there is an absorption of a large amount of the chemical products of decomposition, and embolic suppurations are apt to occur. The septic embolism is rapidly followed by suppuration, which may extend to the entire eye in the form of panophthalmitis. The thrombosis sometimes comes from a microbic area, as in endocarditis or pneumonia. Whether the obstruction occurs in a chorioidal or a retinal vessel can only be determined by the ophthalmoscope at the very beginning of the ocular symptoms. Later this fact can only be demonstrated by microscopical examination.

Goh makes a rather fine-drawn distinction between septic retinitis and septic chorio-retinitis. He says that in septic retinitis there are no acute inflammatory phenomena present, for it is not caused by the local infiltration of bacteria, but by a general blood disturbance of a toxic nature. By this blood disintegration either the capillaries suffer by being deprived of their endothelium and diapedesis occurs, or else marantic thrombi are formed in the veins of the chorioid and retina. Such a thrombosis, however, he thinks is rarely the cause of septic retinitis, when occurring in the retina, but if it occur in the chorioid, it may favor the development of a metastatic inflammation by disturbances in the circulation, especially in the bilateral form of the disease.

Before Goh published his article, it was well known that the retina is peculiarly susceptible to pathological changes in diseases of the general system due to an alteration in the blood, and that the changes in the retinal vessels were secondary to the alteration in the blood. Septic retinitis is more frequently met with than panophthalmitis, and its course is relatively favorable. The foci are small and circumscribed, and the chorioid is rarely involved. It is not due to the formation of emboli, for obstructions of the retinal vessels have never been found. Hence the retinal foci are dependent on some chemical change in the blood. In cases of thrombosis, however, the heart's action is very weak, and the vascular wall, in consequence of the change in the quality of the blood due to the septic process, loses its normal condition, and this is what we find in the chorioidal veins in one or both eyes, the lesion being defined as marantic thrombi. The frequent bilateral character of metastatic chorioiditis is explained in part by the narrowness of calibre of the capillary vessels, and in part by the disposition to clot formation.

Large infectious plugs, which cause a stoppage of the larger vessels, are only occasionally thrown off into the circulation during the course of a pyæmia. The smaller embolic material is much more commonly spread through the general circulation, and takes its own course, independently of the method of division of the larger or smaller arteries. The smaller the vessels, the greater the danger of these smaller clots being arrested. In the region of distribution of the carotid arteries, it has been assumed that metastases are generally rarer than in the internal organs of the body and in the extremities, and the ophthalmic artery would naturally share in this assumption. Only about one-eighth of the amount of blood in the ophthalmic artery goes to the eyeball, which is therefore an organ poor in blood compared to its size. The eye seems less receptive of more compact plugs and more disposed to the occurrence of capillary emboli.

It has been assumed that the occurrence of metastatic ophthalmitis signifies that the general disease has taken on a particularly severe type; but this is doubtful, for, if true, the ocular metastases must then be regarded as of peculiar and unusual importance, and would have a marked prognostic significance.

The frequent bilateral appearance of metastatic

*Read at the meeting of the American Ophthalmological Society, held at New London, July 17, 1901.

chorioiditis, like all bilateral internal ocular lesions, must be regarded as a symptom of a general constitutional condition. In such cases we should expect to find numerous metastases in other parts of the region of distribution of the carotid arteries.

We possess almost no satisfactory anatomical investigations as to what part is played by the eye in the development of metastases. We know that metastatic ophthalmia is met with in influenza, scarlatina, measles, diphtheria, variola, varicella, parotitis, and more rarely in erysipelas and typhoid fever. Of late we have known that it is still more frequently met with in pneumonia and endocarditis.

The irido-chorioiditis, which sometimes occurs in recurrent fever and in rheumatism, is an infectious disease, and may be suppurative, but it never leads to suppuration of the eyeball. The same may be said of the so-called gonorrhœal metastases. Most of these patients do not die, but recover their general health. Hence we have no opportunity for anatomical investigations.

Unilateral isolated metastatic ophthalmia differs in no way from similar isolated purulent foci in other parts of the body, and is not of such vital significance as the bilateral form of the disease. In the rarer form of metastatic inflammation, orbital cellulitis, the exciting cause is the pneumococcus, which has been found in great numbers in the orbital cellular tissue. If the pneumococcus enters the eyeball, the inflammation excited usually runs a mild course, and the cocci which have formed foci of disease subsequently disappear.

The disease, as presented in the six cases which form the basis of this paper, is characterized by pain in the eye and head, intense vascular congestion, with the usual symptoms of chorioiditis or irido-chorioiditis, and rapid and total loss of sight. It may be ushered in by severe headache and vomiting, rise of temperature, and general febrile symptoms. The intra-ocular tension is at first increased, but subsequently sinks much below normal, even when no perforation of the eyeball occurs. The course of the disease is from three to six weeks, and the prognosis is always bad, the case ending in total blindness with a shrunken eyeball. Enucleation of these eyes is not advisable in the acute stage of suppuration, especially if the capsule of Tenon or the orbital tissue be involved.

Case I.—The patient was a boy, aged fourteen, whom I first saw in January, 1901. Three months before he had a severe attack of grippe with high fever which on the third day culminated in pneumonia of the right lung. He was delirious for several days, and when he regained consciousness he was blind in both eyes, and remained so for four days. The sight then began to return in the left eye and rapidly improved, but the vision in the right eye has never been restored. He consulted an oculist, who told him that the right eye had been lost by suppuration, and a yellow reflex was noticed from the pupil. Two days before I saw him the blind eye became red and very painful, and for this he came to the Eye Infirmary. There was then marked ciliary injection, the iris was irregularly dilated and immovable, with posterior synechiæ on the nasal side, and was discolored and of a greenish hue. The cornea and lens were clear, except at the periphery of the latter. The tension was minus 2. There was a very shallow anterior chamber, and the iris bulged at the periphery. There was a yellow reflex from the fundus, with several large vessels running over it. The ophthalmoscope showed the vitreous clear of opacities, and the infiltration involved the chorioid and probably the retina also throughout the entire fundus. Vision in the left eye was $^{20}/_{40}$ and the opthalmoscopic picture was negative. Assuming that the cause of the chorioiditis was the occurrence of one or more arterial or venous obstructions of microbic origin, the comparatively short duration of the blindness in the left eye may possibly be explained by the fact that the vascular obstruction in this eye may have been of small size and that it broke up into smaller masses and passed on in the circulation before any suppurative process began.

Case II.—The patient was a man, aged thirty-two, by occupation a machinist, whom I first saw on January 22, 1901. On December 18, 1900, he was taken ill with symptoms of grippe, which in two days rapidly developed into pneumonia of the right lung. On the eighth day of his illness the right eye became inflamed, with severe pain, great swelling of the lids, and rapid loss of sight. In three days the vision was completely abolished, and there has been no perception of light since. The left eye remained intact, and the vision when tested was normal. When I first saw him the swelling of the lids had nearly disappeared, and the eyeball was somewhat flattened and shrunken. There was no perception of light and the tension was minus 2. The cornea was slightly hazy, the iris was discolored and sluggish, and the lens was clear. There was a dense yellow reflex from the fundus, which extended forward to the ciliary region, over which the retinal vessels could be distinctly traced. The eyeball had perforated below in the inferior quadrant, just back of the ciliary region, and some thin pus was discharged from the inferior cul-de-sac. This pus was examined microscopically, but no bacteria were found in it.

Case III.—The patient was a gentleman, aged forty-two, of frail physique and delicate health, whom I first saw in February, 1899. He was attacked with grippe, which rapidly assumed a serious aspect. Pneumonia developed on the third day, and advanced so rapidly that in forty-eight hours the whole right lung became consolidated. On the morning of the fifth day from the beginning of the attack, the vision of both eyes became affected, and I was sent for. I saw him within two hours after this was noticed, and in both eyes discovered a focus of disease in the chorioid, just above the region of the macula, the media still being perfectly clear. Six hours later I saw him again, and found the vitreous of the right eye so cloudy that no details of the fundus could be made out. The vitreous of the left eye was clear, and remained so until the end, but instead of one focus of chorioidal disease, there were four foci in different parts of the fundus, all posterior to the equator. The next morning the right eye was entirely involved with iritis, pus in the field of the pupil, conjunctival chemosis, and the general appearances of a panophthalmitis with severe pain and no perception of light. In the left eye the entire fundus presented a yellow reflection, as far forward as could be seen with the ophthalmoscope through a dilated iris. The iris itself was not involved, and the picture presented was that of a purulent chorioiditis with a clear vitreous. In the afternoon of this day the left lung became involved, and the patient rapidly sank and died early the next morning, seven days after the attack of grippe began, and five days after the right lung first became involved. By the kindness of the family, I was permitted to remove the right eye for examination.

The eyeball was enucleated in the usual manner, and, after being hardened, was divided nearly in the vertical meridian. The two halves of the eye were then embedded, and about fifty sections were made

stained, and mounted for examination. All the tissues of the eye, with the exception of the lens, were filled with pus cells. In the sclera, chorioid, retina, and optic nerve were numerous lacunæ filled with blood cells. Many veins and arteries in the retina, chorioid, and sclera were plugged with emboli. This was especially noticeable in the retina. There were only a few recognizable rods and cones in the bacillar layer, but the nuclear layers were greatly thickened. The retinal pigment cells were scattered in groups of varying size in the midst of masses of granular exudation. There were groups of pus cells all through the ciliary body and in the vitreous. The chorioid and retina were practically but one layer, as the line of union between the two was obliterated. The micrococci present were the staphylococcus aureus and the streptococcus, and they were found in large numbers in all the tissues, not only in the purulent areas, but also free in the vessels, where they formed the main constituent of the thrombotic and embolic plugs of obstruction.

Case IV.—This patient was a gentleman, aged forty-two, who had always enjoyed excellent health, and, being a man of means, had led a healthful out-of-door life. He was a man of very temperate habits, and denied ever having had any venereal disease. About six months before I saw him, after exposure for many hours to a cold rain storm, while on a hunting trip, he contracted an acute inflammatory arthritis of both knee-joints and the left shoulder-joint, which confined him to bed for six weeks. He had rather a mild endocarditis, which had yielded to treatment, but left him with a mitral murmur. I saw him early in March, 1898, and he then had a rather aggravated conjunctivitis with moderate secretion. This yielded slowly to treatment, but two weeks later he contracted influenza, which showed a high temperature, and on the fifth day pneumonia of the right lung appeared. The disease rapidly extended to the entire lung, and his heart began to labor painfully, with decided irregularity and marked intermissions of the beat. On the fifth day after the pneumonia first appeared, the right eye became red and very painful, with swelling of the lids and chemosis of the ocular conjunctiva. On the sixth day, three foci of suppuration were discovered in the chorioid in the vicinity of the posterior pole, the anterior chamber became shallow, and the aqueous humor turbid. The foci of chorioidal exudation rapidly grew larger, coalesced, and in twenty-four hours the whole fundus was involved, and gave back the characteristic yellow reflex. The next day the whole uveal tract was involved, and there were a number of hemorrhages on the surface of the iris. The tension was at first very much increased, but as soon as the iris and chorioid were involved, the tension sank below normal, and continued about minus 2 until the end. There was slight exophthalmos, but no other evidence of orbital cellulitis. The patient rapidly sank into a septic condition, and finally died of failure of the heart's action. The left eye remained intact throughout. No autopsy was allowed. The marked feature in the case was the very rapid extension of the suppurative process in the chorioid after the appearance of the three foci of disease, and this feature seems to be characteristic of this variety of chorioiditis.

Case V.—The patient was a lad, aged fifteen, whom I first saw in December, 1899. He had always shown a marked tendency to contract the various contagious diseases of childhood, and had suffered from measles, whooping cough, mumps, diphtheria of a mild type, and scarlatina, which left him with diseased kidneys, and albumin and casts in his urine. He contracted grippe for the third time early in December, 1899. It was a rather mild attack, except for a high temperature ($104\frac{3}{5}°$). There were no thoracic symptoms except a bronchial cough until the eleventh day, when consolidation was discovered over a limited region at the base of the right lung. The pneumonia pursued an asthenic, sluggish course, but the consolidation gradually extended to a larger area of the lung, and the patient grew weaker. On the sixth day after the appearance of the pneumonia, the patient complained that the sight of both eyes was affected, and I was sent for. There was a slight ciliary injection and a muddy iris on both sides, but the aqueous and vitreous were clear. The ophthalmoscope showed a large focus of infiltration in the chorioid just above the macula in the *left* eye, and four distinct foci of disease in the chorioid of the *right* eye. These latter rapidly coalesced, and in about fifty hours the entire fundus of both eyes showed the characteristic yellowish reflexion. There were no signs of orbital cellulitis, but in two days both eyes were entirely blind. The high temperature persisted from the beginning, but the process of consolidation was apparently confined to the lower lobe of the right lung. The heart's action was feeble throughout the attack, but there were no signs of endocarditis. The lad slowly sank and died on the ninth day after the pneumonia was discovered. No autopsy was permitted.

The case is interesting from the marked difference shown in the inflammatory process in the lung and in the eye. The pneumonia was confined to the lower lobe of one lung, and pursued its course slowly and without any very marked symptoms except the high temperature. The metastatic chorioiditis showed the rapid progress characteristic of the lesion, ending in total destruction of the vision of both eyes in forty-eight hours.

Case VI.—The patient was a man, aged forty, whom I first saw in March, 1897. He had had a rather mild attack of influenza and was supposed to be convalescing, when, on the ninth day, a suspicious rise of temperature occurred, and he began to cough. An examination showed some consolidation at the base of the left lung. He was kept in bed and carefully watched, but the area of consolidation rapidly extended, and in three days involved the whole of the lower lobe and had invaded the upper lobe. On the sixth day after the pneumonia developed, he complained of failure of vision of the right eye. I saw him about six hours later and found three small foci of infection in the chorioid, one on each side of the optic disc, and one directly at the macula. The media were perfectly clear, the iris was normal in appearance and reaction, and the fundus of the left eye was normal. I examined him again the same evening, and found that two of the foci had increased in size and coalesced. The media were still clear and the rest of the fundus showed no infiltration. The left eye was still intact. The next morning there was a marked change. In the right eye the whole chorioid was infiltrated nearly to the ciliary processes, and the vitreous was slightly cloudy in its posterior part. The iris was not involved, but there was a vivid ciliary injection and engorgement of the deep episcleral vessels as far back as the equator. In the left eye there was a well-marked iritis with adhesions to the lens capsule on the nasal side. The disease pursued a very rapidly destructive course. In the left eye the pupil was blocked by exudation on the next morning, and by the evening of this day all the signs of a septic panophthalmitis were present with some exophthalmos and very severe pain. In the right

eye there was no iritis, but the whole chorioid was involved and the vitreous was very cloudy. On the fourth day after the beginning of the chorioiditis the left eye perforated in the ciliary region below, and the pain then became less severe. There was no perception of light in either eye. The whole left lung was involved, and the patient died comatose on the twelfth day after the first development of the pneumonia. An autopsy was made twenty-four hours after death, and I was permitted to remove the posterior portions of both eyeballs together with the optic nerves and chiasm. There was a very general congestion of the blood vessels of the brain, both on the base and convexity, but no exudation and no signs of meningitis.

After hardening the halves of the eyeballs and the optic nerves, the latter and the chiasm were first carefully examined microscopically, but there was no exudation within the sheath, nor any sign of optic neuritis, and this was confirmed by microscopical examination of many sections. Numerous plugs were found in the smaller vessels of the chorioid and retina in the right eye, and in the left eye every section showed these plugs all over the field in almost every chorioidal vessel. The autopsy also revealed a septic endocarditis which had not been suspected, and here were found numerous streptococci and pneumococci.

In this case the left lung and heart were the seat of the infection. The right eye became first involved, presenting the picture of infectious chorioiditis; while in the left eye the first lesion was an iritis, rapidly followed by a general chorioiditis and panophthalmitis with perforation.

PROTOZOAL LIFE IN THE BLOOD OF MAN AND ANIMALS, AND SOME OF ITS EVOLUTIONARY PHASES IN THE BODIES OF SUCTORIAL INSECTS.*

By M. P. OVERHOLSER, M.D.,
HARRISONVILLE, MO.

All forms of life are included in two great divisions, animal and vegetable. From the largest and highest types of living things down to the minutest forms of microscopic life this same distinction prevails.

In the study of the minute beings of the microscopic world it is only the disease-producing microorganisms that interest the physician. These are also divided into the same two great classes. The first class includes the pathogenic vegetable microorganisms which are called bacteria. The second class includes the disease-producing animal microorganisms which are called protozoa. We thus find that the various and numerous infectious diseases affecting man and animals are either bacterial infections or protozoal infections.

Heretofore the study of the specific microbic agents of disease has been most largely confined to the field of bacteriology. The numerous discoveries, rapid developments, and great achievements in medicine and surgery which have been wrought out by the investigations and study of the life history of the various pathogenic bacterial microorganisms have claimed so much attention of the physicians and surgeons of the present age that the study of the life history of some of the most important and most common protozoal infective agents has been quite neglected.

Recently, however, the announcement of the discoveries of the parasitologists of the present time has revived a new interest in this field of work and we now find that our investigations, pursued with a clearer and more definite understanding of the life cycles of some of the most common protozoal infective microorganisms, are proving to be most interesting, instructive, and practical to the physician.

In this paper I can give but a mere outline of what has been accomplished during the last few years in the study of protozoal parasitic life in the blood of man and various animals, and the great developments that have followed the discovery of a second life cycle of these parasitic microorganisms in the bodies of suctorial insects.

To guard against the use of too many cumbersome and technical terms and to present the subject in a concise and plain manner, avoiding as much as possible a disarranged and confused statement of facts, have been among the points I have endeavored to observe in the preparation of this paper, but in the effort to do this I have been confronted with the difficulty that much of the knowledge we now possess on this subject has been given us by naturalists and scientists who have used the technical terms employed in biology, zoology, and parasitology in giving us the benefit of the knowledge they have gained in their observations and experiments in this line of work.

I therefore ask to be permitted, without criticism, to indulge in the use of terms used by our parasitologists of the present time in the study of this protozoal life, promising as often as convenient to clear up the meaning of obscure technical terms by brief explanation. The protozoa form the lowest division of the animal kingdom and are those organisms which consist of a single cell. The living protoplasm of which they are composed varies considerably in its physical characters. Some are surrounded by a cuticle or shell which serves as a protective covering, others are simply minute naked masses of protoplasmic matter.

The difference in the morphology, life history, and method of reproduction have led zoologists to divide protozoal life into a number of classes or orders. We will not burden our minds with the names, much less the description of any of these great orders, with the exception of one. This one important order embraces the protozoal life we wish to study and is called the order of sporozoa.

All representatives of this order are true parasites, and consist of proper cellular elements made up of protoplasm, a nucleus, and a nucleolus. They have the characteristics of living at the expense of other cells and are therefore true endocellular parasites.

They have an amœboid phase of life and multiply by spores. This group is very widely distributed, being found as parasites in members of all subdivisions of the animal kingdom with but few exceptions. Representatives of this order or class of sporozoa are found in the frog, the tortoise, the carp, the rabbit, the sheep, the ox, the pigeon, the owl, the crow, the sparrow, the lark, the bat, the silk worm, man, and no doubt in many other forms of animal life where they have as yet escaped the eye of the observer.

There are a number of varieties or sub-orders of this sporozoal life. We do not find the same form in birds that we find in reptiles, nor do we find the same form in the ox that we find in man. They differ from each other in many particulars, yet each variety retains the general characteristics of all sporozoal life, and particularly the manner of multiplication by sporulation.

One of the most interesting and valuable discoveries of recent date is the discovery and positive demonstration of two distinct life cycles of some varieties of these sporozoal micro-organisms. The one cycle is completed in the body of some form of

* Read before the Missouri State Medical Association at Jefferson City, Mo., May 23, 1901.

animal life and is called the intracorporeal cycle. The other cycle is completed in the body of some suctorial insect and is called the extracorporeal cycle.

The study of the evolutionary phases of these parasites in the intracorporeal and extracorporeal cycles of their existence has given us the key that has unlocked and unfolded to our view long-hidden secrets of the peculiar life history of some of these protozoal infective agents, a knowledge of which now promises to do as much in the prevention and successful management of one of the most widely spread diseases as any discovery heretofore made in the science of medicine.

From the beginning of the history of our science the symptomatic manifestations of this protozoal life in man have been carefully observed and quite minutely described, but the etiological factor producing the symptoms was not understood and for a long time was believed to be some peculiar form of miasm emanating from stagnant waters and floating in the atmosphere—a bad or *mal* air and for this reason called *malaria*.

There are few terms in medicine so misleading and so unfit to express the true conditions, pathological or etiological, of any disease as the term malaria, but since it has become so fixed in the history of our science and in our medical literature of the present time, and is always applied to those well-marked clinical conditions of the system produced by this parasitic protozoal life in the human body, we will retain the word and use it more generally, applying the same term to all these protozoal infections, whether found in man or animals.

To give us a clearer idea of this protozoal or malarial parasiticism, if you choose, of animal life, we will consider briefly a few interesting sub-orders and species of this great class, sporozoa.

The great scourge of the silkworm, called pebrine, which at one time threatened to destroy the silk industry of France and Italy, was found by Cornelia to be due to protozoal oval parasitic bodies in the tissues of the developed silkworm.

The worm which developed from the infected eggs he found succumbed before the spinning of the cocoons. The great practical result of Pasteur's work in this disease consisted in the demonstration that one could determine by the use of the microscope the uninfected eggs and separate them from the unhealthy ones, so that it became possible to obtain a new breed of worms free from infection.

As a result of the discovery of Cornelia and the investigations of Pasteur, the ravages of this disease have been checked. This sporozoal microorganism belongs to the sub-class of sporozoa called microsporidia, and Theolan says its ravages among the silkworms caused France to suffer a loss of a thousand million francs in thirteen years and Italy a loss of twice this amount in less time.

As we have been taught heretofore to view and name these protozoal sporular infections in the human body this disease called pebrine is simply a malarial parasiticism of the silkworm.

In 1871, a protoplasmic sporozoal life was observed by Ray Lankester in the blood of frogs; it was studied by Danilewsky and has since been found in lizards and turtles. It was observed that the plasmodia developed within the red blood corpuscle and that the intracorpuscular phase of life terminated by sporulation; that is, the parasitic protoplasmic body would divide into a number of segments which formed spores. These spores after being liberated from the corpuscle floated freely in the plasma, reinfecting new corpuscles and thus repeating the same cycle of existence. Some spores it was noticed, however, developed into what are now known as adult forms of the parasite having a vermicular movement and being capable of elongating and enlarging themselves, but reaching no further stage of development in their temporary hosts. It was afterwards learned that these mature forms of the parasite were differentiated into two sexes, and under proper conditions, had the faculty of uniting with each other. These mature bodies are called gametes or gametocytes, and are large and small in size. The larger gametocyte represents the ovule or female element, and is called the macrogametocyte. The smaller gametocyte represents the spermatozoon or male element and is called the microgametocyte. In the intracorpuscular or endoglobular phase of this protoplasmic parasitic life multiplication by sporulation takes place with the liberation of sporules or amœbulæ into the plasma, where they again reinfect new corpuscles, some of which pass on through the same process of sporulation, others of which develop into differentiated adult parasites for propagation of the species outside of its temporary host. This constitutes the first cycle of existence of these peculiar sporozoal micro-organisms.

The second life cycle, in which the elements of fecundation unite, producing a new generation of innumerable sporozoites, takes place in the body of a second or definitive host, so far always known to be some kind of a suctorial insect. Those plasmodial microorganisms found in the blood of frogs and other reptiles are called hæmosporidia, and to apply the same term to the diseased condition in these forms of animal life as we have been taught to use for similar infections in man, we must call it *batrachian* or *reptilian malaria*.

In 1885, Danilewsky observed in the nucleated red corpuscles of birds clear bodies lying on one side of the nucleus and curved over its ends, thus having a crescentic shape. Grassi and Felleti, in 1890, described a second form of organism, smaller and more irregular in size, lying at one end of the corpuscle and displacing the nucleus to the other.

This type of protozoal life has been observed in a great variety of avian species—sparrows, pigeons, owls, crows, etc. These parasites have a life history very similar to that of those found in reptiles. They are also endoglobular or intracorpuscular parasites, which nourish themselves at the expense of the hæmoglobin of the red blood corpuscle, converting its coloring matter into melanin, thus gradually diminishing its normal hæmoglobinic tint and finally destroying the corpuscle by the process of segmentation and sporulation.

We find here, as we find in reptilian malaria, adult forms of the parasite which are capable of no further development in their temporary host, and which represent the end product of the first cycle of this parasitic life. These oodies float free in the plasma with no office to perform except to wait for their transmission to their second or definitive host where fertilization of the macrogametocyte results in a fresh crop of sporozoites.

Ross found that the second life cycle of hæmosporidia of birds was completed in the body of the culex pipiens, a variety of mosquito.

It is known that blood containing microgametocytes and macrogametocytes taken from infected birds by this variety of mosquito finds in the mid-intestine of the mosquito all the conditions necessary for the proper union of these sexual elements which results in the formation of a zygote or sporocyst, inside of which are developed an immense number of zygotoblasts or sporozoites. On the rupture of the zygote or sporocyst the zygotoblasts or sporozoites become free in the body of the mosquito, filling the salivary ducts,

and there await their inoculation into the next avian victim bitten by the infected mosquito.

Volumes have been written on the subject of hæmocytozoan or hæmosporidian infection of birds alone. It is, as we have shown in other forms of life, an intracorpuscular protozoal infection, and again using the same term we have been taught to apply to these infections in the human body, it is most properly called *avian malaria*.

In 1889, Theobald Smith discovered an endoglobular parasite in the blood of cattle suffering from Texas fever. These parasitic agents are found to be homogeneous pale bodies of a pyriform outline, one end being round and the other tapering to a point. Usually two such bodies are found in the same corpuscle lying with their pointed ends together but not apparently in continuity.

This disease has a wide geographical distribution, being found in the Southern States and in parts of Europe and Africa. It may assume an acute, rapidly fatal form, running its course in three or four days, being characterized by fever, rapid destruction of red corpuscles, hæmaturia, hæmoglobinuria, and at autopsy great enlargement of the spleen may be found. This disease of cattle has been carefully studied by Smith and Kilborn, who have shown that the disease is transmitted by a special tick, Boophilus bovis, or the cattle tick.

They have proved that a diseased animal from which all ticks are carefully removed does not infect a healthy animal; that fields may be infected by carrying to them ticks taken from diseased cattle; that young ticks born of mothers nourished upon diseased cattle produce Texas fever when they are placed upon susceptible cattle. These men have proven conclusively that the adult tick, after living upon the skin of an infected animal, upon whose blood it feeds, when it drops to the ground and lays its eggs transmits the infection to its progeny, and the younger ticks developing from the eggs of an infected mother tick are capable of inoculating the disease into healthy animals.

We thus see that the life history of the protozoal parasite producing Texas fever of cattle embraces also two distinct cycles; one cycle is completed in the body of the ox, the temporary host of the parasite; the other cycle is completed in the body of the cattle tick, the permanent host of the parasite.

This disease may destroy a whole herd of susceptible cattle, and is only another variety of the same great class of sporular protozoal infections, and can be most appropriately named *bovine malaria*. Kolle has found other endoglobular parasites somewhat different from the preceding in calves.

It has long been known also among the shepherds of Italy that young lambs feeding in marshy places were subject to a severe and fatal anæmia, which has since been proven to be due to destruction of the red blood corpuscles by protozoal parasites.

There are still other animals subject to this infection, but I have cited, I think, examples sufficient to prove the existence and similarity of these protozoal diseases in all subdivisions of the animal kingdom. It is thus plainly seen and acknowledged by all who have studied and investigated this subject for themselves, that protozoal endoglobular parasiticism is very widely diffused throughout the animal kingdom, from reptiles to man.

For the physician the most interesting and most practical part of the study of protozoal intracorpuscular parasiticism is found in the study of human malaria.

In 1880, Laveran, a French military surgeon stationed in Algiers, discovered the malarial protozoan microorganism in the blood of man.

We find much of interest in the early history of the researches of malarial affections, and on through the ages down to the present time; but the time is too limited to attempt to present even a short historical sketch on this disease; suffice it to say that in the most ancient period of its history we find that Empedocles of Agrigento, five hundred years B. C., discovered the injurious effects of stagnant water upon the health of man and is said to have delivered his city from an epidemic of fever by draining the stagnant water of the surrounding country.

The next great discovery was the specific remedy for the disease and the introduction of cinchona bark into Europe toward the middle of the eighteenth century.

The third important discovery was that of Laveran, a little over twenty years ago, who found the parasite in the blood.

The last and quite recent discovery, and one which promises to do more than any other in the prevention and eradication of this disease, is that of the transmission of infection solely by the anopheles mosquito.

Grassi says the importance of this discovery cannot be overestimated. "If throughout the length and breadth of the Italian peninsula, where nature smiles so maternally, this dreaded disease, which claims 15,000 of our inhabitants annually and has depopulated and rendered uninhabitable certain of our districts, can now be subdued, every acre of our prolific soil can be utilized and a great future, far beyond even the most enthusiastic expectation, will open up for our country. Beyond this, the eradication of malaria will make the tropics habitable for all classes of men, and greatly favor the advancement of civilization and culture throughout the earth."

The water theory and air theory of infection have both been exploded. Celli had healthy individuals in the Santo Spirito Hospital drink for several days water collected in the Pontine marshes and from stagnant pools near Rome, but with negative results. Zeri, at the suggestion of Celli, carried out three series of experiments. He had nine persons drink for from five to twenty-five days one and one-half to three quarts daily of water taken from malarious places so that each person ingested from ten to sixty quarts of stagnant water. He sprayed the mucous membrane of the respiratory apparatus with marsh water by means of an ordinary compressed atomizer, experimenting in this way on sixteen individuals. In five persons he experimented with rectal injections of water from malarial regions. In none of these cases was he successful in producing a single attack of malaria.

To prove the infection by the sting of the mosquito, Bignami transported infected mosquitos from a place where malaria prevailed to positively non-malarious districts, where healthy men were bitten by the infected mosquitos and soon developed malaria. He then took healthy men from non-malarious districts, whose blood was found free from malarial plasmodia by repeated microscopical examinations, and transported them to malarious regions, where he kept them free from infection for an indefinite period of time by confining them day and night in fine screen cages where the malarial mosquito could not reach them.

After positively demonstrating that these patients could not contract malaria from the air or water or food of these highly malarious districts, he then liberated malarial-infected mosquitos in the screen cages of these patients, and after a proper time, they developed the clinical symptoms of malaria,

and the microscopical examination of the blood showed malarial plasmodia.

That this insect, the mosquito, was somehow concerned in the production of malarial disease has long been conjectured. Its association with swamps, with high atmospheric temperatures, its geographical distribution, its nocturnal habits, and other circumstances had forced this conclusion on many minds long ago. Certain savages even recognized the connection and believing that malarial fever was caused by the mosquito, gave the disease and the insect the same name, but it was not until experiments were made like those I have cited that the manner of infection was positively demonstrated, and it was conclusively proved that the only mechanism by which malarial infection of the human body can be acquired is by inoculation. This means that the extermination of the malarial mosquito will lead to eradication of human malaria.

By the advice of Celli and others the government of his country is now enacting laws and taking such steps as are necessary to annihilate this recently dreaded little propagator and inoculator of these malarial protozoal microorganisms.

We find three chief varieties of the malarial parasite in man. The cycle of endoglobular life of one variety is forty-eight hours; that is, it requires forty-eight hours for the young amœbæ, after they enter the corpuscles, to pass through their process of growth, segmentation, and sporulation. In malaria it is the process of sporulation, with liberation of a new crop of sporules or amœbulæ in the plasma that produces the chill and fever. This type of fever, in which sporulation of plasmodia takes place every forty-eight hours, is called the tertian.

The quartian species of plasmodia requires seventy-two hours from the beginning to the end of its intracorpuscular life; that is, three days for the completion of the process of growth, segmentation, and sporulation.

The quotidian, or every-day chills and fever, is simply a double tertian; that is, two generations of the same variety of parasite in the same individual, one generation sporulating one day and the other generation sporulating the next day.

The third variety of malaria called the estivo-autumnal is the most peculiar, insidious, and deceiving, I dare say, of all the infections of the human body with which we have to deal. It is now beyond question that the clinical phenomena of this particular species of plasmodial life are so varied, so irregular, and so misleading in their manifestations, that frequently they deceive the most expert diagnosticians, and nothing but a microscopical examination of the blood can reveal the true nature of the trouble.

Mrs. C., aged thirty-eight years, had not been well for seven or eight weeks; she complained of weakness and nervousness, pain in the back of the head, numb, tingling sensations in the limbs, various paræsthesias confined mostly to the left side of the body, "bilious-like spells," with coated tongue, and irregular action of the heart. One night the patient was suddenly taken with a violent and persistent attack of muscular tremor and twitching of the muscles of both arms and hands; temperature and pulse were normal, and the mind was perfectly clear. Two hypodermic injections of one-quarter grain each of morphine with bromides were required before the clonicotonic convulsions of the arms and hands ceased. The patient had had a similar spell a week or ten days previously. The first interpretation of the symptoms was that they were hysterical. A microscopical examination of the blood, however, showed intense estivo-autumnal infection. In some microscopical fields nearly every corpuscle was found infected. The plasmodia were in the shape of small discs, small transverse rods, curved rods, S-shaped, triangular, and many other irregularly shaped forms, numerous gametocytes, pigmented leucocytes, and diminished hæmoglobinic tint of the red blood corpuscles, with innumerable free sporules in the plasma. The patient improved rapidly in a comparatively short time under rigid anti-malarial treatment.

Mr. S., age fifty-three, was confined to his bed for a number of weeks with severe pains in the region of the stomach and gradual loss of flesh. The pains were frequently so severe that the patient could not sleep for hours at night. The appetite was fair and the bowels were regular, yet, from the location and character of the pains, the emaciation and age of the patient, competent physicians suspected incipent malignant trouble in the stomach.

The patient finally recovered sufficiently to get up, but continued very weak and did not seem to improve. He stated that he had but little fever during his sickness. At the time of examination, several months after the beginning of his illness, the temperature was 97.5°, pulse 104, the appetite was good, but the patient was very weak. Examination of the blood revealed malarial plasmodia most abundant. The infected corpuscles were numerous, sporules innumerable in the plasma, crescents, and fully developed gametocytes in large numbers. The patient improved at once on anti-malarial treatment.

Mrs. M., married, no children, complained for over three years of attacks of vertigo, "weak spells," "nervous headaches," pains in the stomach radiating up over the chest, pains in the intercostal spaces, and in the lumbar regions. The patient became frequently prostrated from these pains and vertiginous attacks. The bowels were fairly regular and the appetite was good most of the time. She was treated for several years for dyspeptic vertigo, neurasthenia, etc. Examination of the blood showed hæmoglobin forty per cent., red blood corpuscles 2,880,000 per cubic millimeter. The patient was markedly anæmic. Further examination of the blood proved the fact that the anæmia was due to a destruction of the red blood corpuscles by the estivo-autumnal malarial parasite.

A diagnosis was made of marked anæmia with lumbar, gastric, and intercostal neuralgias, vertigo, and general neurasthenia due to chronic malaria. Chalybeate tonics, and anti-malarial treatment restored the patient to fairly good health after some months of treatment.

A man, aged forty-five years, was taken very suddenly one night during the month of July with severe cramping pains in the stomach and bowels, vomiting, frequent copious watery discharges from the bowels, and great prostration. The temperature was subnormal. The case resembled one of ptomain poisoning. Examination of the blood showed intense malarial infection. A diagnosis of choleraic pernicious malaria was made. Appropriate treatment was followed by rapid recovery.

A babe nine days old began to be restless. The restlessness was followed by severe crying spells, and the child began to lose flesh and fail in strength. The breast-milk was thought insufficient for nourishment and a preparation of milk, cream, and water was given in addition to milk from the breast. The baby continued to grow worse with an elevated temperature and abnormal fermentation in the bowels with green, thin, offensive discharges mingled with curdled milk. Laxatives and intestinal antiseptics were prescribed. On the sixteenth day the friends noticed several

attacks of "twitching of the hands and feet" which developed into a pronounced convulsion on the following day. Immediately following the convulsion the child had violent persistent clonic contractions of the muscles of the hands, arms, lower limbs, head, and neck, with a tendency to opisthotonos.

The general clonicotonic convulsions continued for ninety-six hours with no intermission—four days and four nights. The morning temperature was 100°, evening temperature 102° to 103° and as high as 104°. The child being too weak to nurse was given a rich artificial food, consisting of cow's milk, cream, and prepared food. Quinine was given during the earlier part of the sickness in doses of one-sixth, one-fourth, and then increased to one-half grain every two or three hours with no apparent effect. As bromides and sedatives did not improve the condition of the child, quinine was then increased to one grain every two hours, the little patient, less than three weeks of age, receiving twelve grains of quinine by the stomach in twenty-four hours. As I felt satisfied that the case was one of eclamptic pernicious malaria, the disease not yielding to this treatment, five to eight grains of quinine in addition were given per rectum two or three times in the twenty-four hours for several days. Under this treatment the convulsions gradually grew less and finally ceased so that by the twenty-fourth day the child was again nursing and is now a fat hearty baby eight months old. I may add that, some weeks previous to the birth of the child, the mother asked me to prescribe for her, at which time I made a microscopical examination of her blood and found it contained the estivo-autumnal germ. Quinine and tonics were then prescribed with apparent recovery.

In another case a little babe several hours after it was born began crying violently as if in severe pain; an action of the bowels gave little relief. The crying spells would recur every afternoon and evening about five, six, or seven o'clock and would continue for hours at a time. The usual remedies for "colic" gave no permanent relief. The crying spells continued to recur each evening and night until the mother and friends were fully satisfied that the babe was born with the "three months' colic." The temperature was normal; green discharges from the bowels and slight subconjunctival hemorrhages were among the symptoms. An examination of the blood of this babe microscopically revealed marked estivo-autumnal malarial infection, fully developed gametocytes, numerous infected corpuscles and innumerable sporules in the plasma. Quinine in good doses internally cured the so-called colic almost like magic. It was only necessary to repeat the treatment for several days each week for some time to prevent the recurrence of the attacks.

I wish to say here that, in this section of the country, in the so-called intestinal colic of babes under six months of age or older, where these little ones have intermittently prolonged spells of crying day after day and night after night for weeks at a time, quinine will give more permanent benefit in the great majority of cases than all the modifications of food that can be made, or any other single remedy or set of remedies named in our pharmacopœia. I dare say a careful microscopical examination of the blood of these little suffering patients will convince the most skeptical of the true etiological factor in many of these cases.

I will conclude with the report of the following case:

Mr. N., age seventy-seven years, complained for several months of shortness of breath, "wheezing in the lungs," cough, restlessness, and sleeplessness at night. The usual remedies prescribed for cough gave some relief. Some weeks later, however, the patient grew worse, dyspnœa continued and grew more distressing, and œdema of the lower limbs developed, the swelling extended to the knee. Examination of the urine showed a specific gravity of 1.022, acid reaction, urea .023 grams per cubic centimeter, or about eleven grains per ounce, chlorides, ten per cent. Albumin was present, but not abundant. Microscopical examination showed granular and hyaline casts. The temperature was normal. Infusion of digitalis and citrate of potassium, other diuretics, and heart-tonics with saline laxatives gave little relief. On careful examination of the blood intense estivo-autumnal infection was discovered. There were innumerable infected corpuscles, fully developed differentiated gametocytes, melaniferous leucocytes and plasma swarming with sporules. Rigid anti-malarial treatment, consisting of quinine, iron, strychnine, etc., with other arterial tonics, internally supplemented with subcutaneous injections of quinine bisulphate in twenty and thirty-grain doses every few days have improved the condition of the patient markedly and I trust in time will restore him to his usual health.

Rempicci, of the Roman Medical Clinic, studied three hundred and fifty cases of malarial infection and found out of this number eighty cases with renal lesions due to malaria. Bartels believes malarial infection to be one of the most active causes of chronic parenchymatous nephritis. But be that as it may, it can now be no longer doubted that acute and chronic nephritis with œdema of the lower extremities, marked anæmia, distressing dyspnœa, congestion of the lungs, and death is quite frequently due to this peculiarly insidious pernicious malarial germ.

As there is no further time to multiply cases I will simply state that, in addition to the clinical forms of this infection above described, we have the dysenteric, gastric, tetanic, hemorrhagic, apoplectic, hemiplegic, cardialgic, neuralgic, lethargic, comatose, algid, syncopal, articular, and many other symptomatic manifestations of the activity of this protozoan germ in the blood of the human body.

There are few fields in medicine so little studied that are so rich in facts, so interesting to the true investigator, and so productive of good results to the physician as a careful microscopical examination and close study of this protozoal life in the blood of man.

SUGGESTIONS IN INFANT FEEDING.

By CHARLES GILMORE KERLEY, M.D.,

NEW YORK.

LECTURER ON DISEASES OF CHILDREN, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; ASSISTANT ATTENDING PHYSICIAN BABIES' HOSPITAL, NEW YORK; PHYSICIAN OUT-PATIENT DEPARTMENT, BABIES' HOSPITAL, NEW YORK.

NATURE has decreed that the food of all young mammals shall consist of certain definite elementary substances—fat, proteid, sugar, inorganic salts, and water. These substances, combined for the use of the young mammal, form what is known as milk, a food suitable for its growth and early development—a food which the young animal has a right to demand, and when it is not furnished in good quality and suitable amount, the animal fails to thrive. The infant demands the mother's milk. If this is not to be had, we must supply a substitute possessing at least approximately its nutritional elements. Average mother's milk contains 3.5 to 4. of fat, 1.5 of proteid and 7. of sugar. In selecting a food for an infant we must imitate nature, and if we are to do this with any degree of success we must know what the substitute contains. It is an unscientific and careless practice to order this or that food or this or that milk formula and not know the nutritional contents.

Cow's milk is the best available substitute. Average

cow's milk contains approximately 4. of fat, 4. of proteid, and 4. of sugar—more than twice as much proteid as mother's milk and of a different character, and about half the amount of sugar. The changing of the relative proportions of the chief nutritional factors in cow's milk so that they will correspond in amount to the fat, sugar, and proteid in mother's milk, has given rise to the term "modified milk," a term which has been the cause of no little confusion, for the reason that it expresses very inadequately what is accomplished when cow's milk is made acceptable for a baby.

Modified milk conveys to the mind the suggestion of a definite product, something the result of a fixed formula. I have repeatedly been asked at the Polyclinic and elsewhere for the formulæ of modified milk and of laboratory milk. If modifying or mechanically changing the proportions of fat, sugar, and proteid in cow's milk so that they corresponded to those of human milk, were all that is required in infant feeding, the matter would be most simple. A term which cannot be confused and which explains fully what we hope to accomplish in our milk manipulations is "adapted milk." The milk is adapted to the child's digestive capacity and requirements.

Pediatric writers and teachers, in their enthusiasm with percentage methods and milk formulæ, have been entirely too technical in this teaching, and have not greatly advanced the knowledge of infant feeding by the use of cow's milk among the profession at large. They have issued series after series of intricate formulæ to be used in definite amount at the various ages of infancy, but have devoted surprisingly little attention to the infant who is to be fed, or to the instruction of the physician as to how he is to judge of the child's food capacity, or how he is to meet the many phases of the infant's digestive peculiarities.

There can be no set formulæ for the various ages of infancy. For this to be possible, it would mean that all infants must be socially, financially, and physically alike, living in one climate, having but one season. Further, among infants living under like conditions, one will require stronger food than another of the same age and weight, one child will have a weak proteid and high fat capacity, another will have a low fat capacity and high proteid. One will thrive as well as the other when the food is properly adapted.

The teaching of set formulæ is dangerous for the reason that no distinction is made as regards food strength for the different months of the year. During the hot months the digestive capacity of every infant is lessened. All bottle-fed children under my care receive from 10 to 20 per cent. weaker food during July and August and early September than is given at other seasons of the year. They are given the same in amount as at other times, but of a weaker strength, particularly as concerns the proteid. Every mother of a bottle-fed baby is told he will gain but little, if at all, during the above period. She is also assured that the chances of summer diarrhœa by this precaution will be reduced to a minimum, over-feeding being one of the fruitful causes of summer diarrhœa according to my observations.

Many of the formulæ suggested are very difficult of comprehension, and others are so impracticable as to be impossible of use in a family. The impossibility of understanding some of the feeding schemes suggested, the impracticability of others, and the bad results attending the use of those which can be understood, have discouraged the practitioner in the matter of cow's-milk feeding.

In feeding a baby other things have to be taken into consideration than the adaptation or preparation of the milk. The social conditions, the financial, and the mental capacity of the mother must be passed upon. I have out-patient children whose mothers cannot afford to buy cow's milk; I have out-patient children whose mothers have not the time, or will not take the trouble, to manipulate cow's milk, cream, and milk-sugar if they can afford it; I have those who are not sufficently intelligent to prepare an adapted food if they have the means; others cannot afford ice, and have no ice chest if ice were given them. The children of the poor and the ignorant must be fed, and we must instruct the mother as to the best available means. If she can purchase cow's milk, she is advised as to its use; our instructions are to use it thinned, diluted with a cereal water to which sugar is added. This gives a weak fat food, the fat being supplemented, except during the hot months, by the use of cod-liver oil. If cow's milk is not within the means of the mother, condensed milk is substituted. A ten-cent can of condensed milk will supply food for from two to three days, and will keep sweet during this period. The child will live on it, and some thrive fairly well for a short time. The condensed milk is also supplemented with cod-liver oil. I have yet to see a child, however—and I have critically examined thousands of them—who had been fed exclusively on the proprietary foods or condensed milk, for a period of three or four months or more, who did not show some signs of malnutrition. They are usually undersized, rachitic, have poorly developed and flabby muscles, and show a loss of inhibitory control.

Given an intelligent mother or nurse, with means to buy milk and ability to prepare it, there is but one substitute for breast-feeding. Physicians must learn, in order successfully to feed infants, what cream and milk contain, and then in an average feeding case they must combine milk, cream, water, and sugar in such proportions that the relative strength of the fat, sugar, and proteid as found in mother's milk is maintained, regardless of the general strength. Thus, mother's milk contains about twice as much sugar as fat and about two and one-half times as much fat as proteid.

Beginning with the feeding of the child at birth, for the first three days one-half per cent. of sugar-water mixture is given; after the third day a milk mixture containing 1. of fat, .4 proteid, 4.5 sugar; after the tenth day 1.5 fat, .7 proteid, 5. sugar; after the twenty-first day 2. fat, .8 proteid, and 5. sugar. The increase, as will be seen, is very gradual, so that when the average child is six months old he will receive 3. to 3.5 of fat, 1. to 1.5 of proteid, and 7. of sugar. A very weak strength is given at first, which is increased if the child thrives. The baby is weighed every two or three days, and the stools are examined daily for signs of indigestion. The fat, proteid, and sugar are independently increased or diminished as may be indicated by the stools and the condition of the patient.

When this method of low feeding is brought into use at birth, it is with very few exceptions followed by success—in fact, I have had but two children whom I could not feed with cow's milk when I had an opportunity to control the preparation of the milk from the beginning of life. These two cases will be referred to again.

The most usual error is in beginning at birth with too strong a milk mixture, and in inattention to the case. In too many instances the nurse assumes charge and feeds the baby as she pleases. Indigestion, evidenced by colic, diarrhœa, and vomiting, result; cow's milk is said not to agree, and then begins a series of food changes, after each trial of which the child is a little worse off than before.

The milk used for an infant's food should be handled as little as possible. I prefer milk and

cream which has not been subjected to the centrifugal process.

For the preparation of food two bottles of the best milk obtainable are required daily. From the top of one bottle all the cream is removed. If milk of the best quality is selected, the entire gravity cream will contain approximately 16. fat, 3.2 proteid, and 3.2 sugar. All the cream must be removed, for the reason that that nearest the top of the bottle is much richer in fat than that which adjoins the milk. It is best for the mother or nurse to raise the cream at home. Cream purchased as such is often older than the milk with which it is mixed, and unless it comes from the laboratory its use is unsafe from every standpoint. The remaining bottle supplies the milk; full milk only is used. Before opening the bottle it should be thoroughly shaken so as to mix well the milk and the separated cream. The full milk contains approximately 4. fat, 4. proteid, and 4. sugar.

One pint contains 16 oz., with which every mother and nurse is familiar, and this measure of one pint is used as a basis of measure in our calculation.

	Fat.	Proteid.	Sugar.
8 oz. milk 8 oz. water 16	=2.	2.	2.
4 oz. milk 12 oz. water 16	=1.	1	1
2 oz. milk 14 oz. water 16	=.5	.5	.5

Gravity cream contains—

	Fat. 16.	Proteid. 3.2	Sugar 3.2
1 oz. cream 15 water 16	=1.	.2	.2
2 oz. cream 14 water 16	=2.	.4	4
1 oz. cream 2 oz. milk 13 oz. water 16	=1.5	.7	.7
2 oz. cream 2 oz. milk 12 oz. water 16	=2.5	.9	.9
2 oz. cream 4 oz. milk 10 oz. water 16	=3.	1.4	1.4
3 oz. cream 2 oz. milk 11 oz. water 16	=3.5	1 1	1 1

Sugar is added in quantity from 5. to 5.5 as the individual may require. When more than one pint of the food is required for the twenty-four hours, multiples of the substances can be used.

Absolute percentage accuracy is not claimed here. The table is given to show practitioners the nutritional value of certain combinations of cream, milk, and water.

Sterilization and Pasteurization.—By sterilization we understand the heating of milk to 212° and maintaining this temperature for thirty minutes. By pasteurization we understand the heating of milk not higher than 167° F. and keeping it at this point for thirty minutes. Unfortunately, in New York City we are obliged to heat milk. I believe non-sterilization to be a dangerous teaching at any season of the year if the uncertain milk of the market is used. During the hot months all milk should be heated to at least 155° and kept at that point for twenty minutes. Milk is unquestionably rendered more indigestible by heating, but is nevertheless safer to use. It will keep sweet longer, and many harmful bacteria are destroyed.

We constantly meet children whose digestive powers have been so reduced by bad management that the digestion of cow's milk in sufficient quantity for the child to thrive is impossible. In these the trouble is usually with the casein. Is there any process by which milk may be treated so that the child may be assisted in the digeston of casein?

Two methods have their advocates. The *peptonizing* of milk, and the use of *cereals*. Peptonizing, in my hands, is without value except in those cases in which completely peptonized milk is introduced into the stomach by gavage, or into the rectum. If the milk proteid is peptonized it is converted into peptone, producing a bitter product which the child will not take. Partially peptonized milk is a term for an impossibility. We have peptone or we do not have it. If we do not have it, we have proteid, which is the cause of the trouble. I have tried various peptonizing processes in many children, and have yet to be convinced that it is of any value. Given a very delicate child, one of our difficult feeding cases, and we *cannot* give a stronger proteid by the aid of any peptonizing process.

Cereals.—Much has been written regarding the value of cereals as diluents of cow's milk, the theory being that the cereal causes the proteid to break up into finer, more flocculent curd, and the digestive juices can then more readily come in contact with the proteid particles. In a test tube this makes a very pretty demonstration, and a finer division is certainly produced; but the production of a finer division of the curd does not constitute proteid digestion. The difficulty in these cases of proteid indigestion does not rest in mechanical coagulation, but in a weak and in some cases an apparent absence of the protolytic ferments. During the past thirteen years I have fed a few thousand babies from all the walks of life during all seasons of the year. Cereal gruels have been extensively used as diluents, and they have been found useful in infant dietetics because of the nutrition that they furnish. Barley water, two tablespoonfuls of barley to the pint, contains approximately .7 per cent. of fat, 3 of proteid and 2. of soluble carbohydrates. By the use of cereals, however, I have never been able to increase the proteid in a case of proteid incapacity.

You ask how is a baby to be fed who cannot digest cow's milk proteid? Cow's milk as well as mother's milk contains two proteids—casein, the curd-forming element, and difficult of digestion, and lactalbumin, which is in solution and is comparatively easy of digestion. Mother's milk contains about 1. of lactalbumin and .5 casein; cow's milk contains about 3. casein and 1. lactalbumin. It is this large amount of casein, this disproportion of the two proteids in cow's milk as compared with mother's milk, which gives us the trouble. If we are to feed cow's milk to not a few delicate infants the casein must be removed. This is accomplished in the use of rennet or pepsin, and moderate heat. The milk is converted into curds and whey. The curd or coagulated casein is removed; the whey which remains contains about 1. of fat, 1. of lactalbumin and 4. of sugar. This gives us a food weak in fat, but with a proteid which is exceedingly easy of digestion. The weak fat is increased as soon as possible by the use of cream.

Signs of Faulty Feeding.—In some instances it is

almost impossible to differentiate just what is wrong with the food which is not agreeing with the child. In the great majority of cases, however, a fairly correct diagnosis is possible. The food may be too strong or too weak, either fat, proteid, or sugar may be in excess, or the relative proportions of fat, proteid, and sugar may not have been maintained. These various errors have a few symptoms in common if the case is of some duration. We are apt to see regurgitation of food, undigested stools, colic, and malnutrition. Individualizing symptoms, however, are often sufficiently pronounced to enable us to differentiate. If the milk mixture as a whole is too strong, a prominent symptom is loss of appetite, the child will not take the usual allowance, it is satisfied with one-half to one-third the amount, and if more is forced it vomits.

Fat in excess or fat incapacity almost invariably causes active peristalsis—colic and green stools result, sometimes a dozen or more a day, and we are told by the mother or nurse that every napkin removed is soiled a little. Excessive fat may produce regurgitation of sour whey in which the fat particles will be found floating.

Proteid in excess of digestive capacity is the chief cause of trouble in cow's milk feeding. If the proteid is properly adjusted the fat and sugar are not apt to give trouble. Proteid or casein indigestion produces colic. Habitual colic, almost without exception, means proteid indigestion. It is one of the most usual causes of habitual constipation. Sugar of milk alone is rarely the cause of trouble when given with any degree of reason. The digestive power of the weakest child for sugar is surprisingly good. If there is sugar in excess or sugar incapacity the regurgitation of sour watery fluid mixed with mucus may take place.

When the relative proportions of fat, sugar, and proteid have not been respected in the milk mixture, indigestion may result. Except in cases of special incapacity, there should be, as mentioned above, about twice as much sugar as fat, and about two and one-half times as much fat as proteid. I have found the digestion to be carried on much better under these conditions regardless of the general strength of the mixture; thus, if one were to give 1.5 fat, 1.5 proteid, and 1.5 sugar, the digestion of the proteid would not be as complete and with as little disturbance as when the fat and sugar are where they should be.

Difficult Feeding Cases.—The difficult cases are those in children who have been badly fed, usually for several weeks or months. They require an almost endless amount of patience on the part of the physician and mother. The story is that of a baby born at term, strong and well; the mother could not nurse him, and he was given cow's milk, always too strong; he failed to thrive, vomited, had colic or diarrhœa—one or both—and cow's milk was said not to agree. He was then put through a series of changes, including the use of condensed milk and the various foods, until we have a baby perhaps ten months of age weighing but a pound or two more than at birth, with all the signs of malnutrition. He sleeps badly, cries and worries a greater part of the time when awake; he regurgitates or vomits or refuses the food. He may be voraciously hungry, taking a large amount and throwing up part of it. He has never had a normal stool—they are composed of a greenish mucus mixed with curds; sometimes he has diarrhœa, sometimes constipation. We have a thoroughly miserable and unhappy baby for a patient.

A case which recently came under my care represents very well this type, and is also an argument against set formulæ. The baby was six months old and weighed ten pounds—he should have weighed fifteen. He never was nursed. [illegible]w's milk and cream in the use of the materna were given, according to the directions on the panels, corresponding to its age. The mixture proved too strong, particularly in proteid, and the child suffered from colic, indigestion, and constipation. He developed rickets to a marked degree. About a month before coming under my care, an extra allowance of cream was added to relieve constipation, so that he received from a 5. to 6. fat, 2. to 3. proteid, and 7. of sugar. As a result of the excessive feeding, which, with too weak feeding, is equally a cause of malnutrition, various nervous manifestations were induced, among which laryngismus stridulus was prominent, and when I saw him he was having from eight to ten attacks of laryngismus daily.

The management of these extreme cases is as follows: A careful history is taken and recorded; the child is stripped, examined, weighed, and the findings recorded. The child was brought with the hope that a food might be suggested which would agree. What are we to do? Give the untried foods on the market or some other preparation of milk in the hope of striking upon something that the child can thrive upon? Not at all. The stomach is washed, whether there is vomiting or not, and for from twelve to twenty-four hours nothing but plain water or a dextrinized cereal water is given. If the case is one of apparent indigestion, whey perhaps will be given. Whatever the diet selected, written directions are given the mother or nurse for its preparation, and as to the time and quantity of its administration. The child must be seen every day, and the stools examined daily. He is weighed every other day; at first no gain will be made and the mother and nurse must be advised that none will be expected. Sometimes there will be a slight loss, which does not concern us. The worst cases of this type are usually given a dextrinized cereal water and kept on this for several days, and when the child's condition warrants the use of milk it is cautiously added, not one-third milk and two-thirds water, or even one-fifth milk and four-fifths water. From one-half to one teaspoonful of milk is added at each feeding, or perhaps every other feeding. If this agrees, in from twenty-four to forty-eight hours the amount will be increased to two teaspoonfuls, then to three, four and more. If whey is selected, it will be increased in strength; in the use of cream, one-half to one teaspoonful of gravity cream will be added to each feeding and increased as the conditions allow.

In assuming care of one of these difficult feeding cases, it should be impressed upon the parents that the child must be seen every day or two—under no other conditions will I assume charge of such a patient.

Recently I have been employing daily stomach washing in chronic indigestion with much benefit, regardless of the matter of vomiting. More food is taken, and it is digested better; it is often surprising to note the large amount of mucus removed from the stomach of an infant who is not vomiting.

I have infants under my care who receive a weaker food late in the afternoon and evening than in the morning. This suggestion will be found very useful in the case of evening colic. The child is well and happy during the day, but toward evening he becomes restless, cries a great deal, and perhaps has a severe attack of colic lasting an hour or two. Such attacks are to be explained by the fact that the digestive organs are tired after the day's work and weaker food will be taken without inconvenience. This is another point against set formulæ. In a few evening colic cases I have given an evening feeding

of one-third broth and two-thirds barley-water in order that the stomach may rest.

One of the most obstinate feeding cases under my care is an eighteen months old child living in a New Jersey town, who is fed two-thirds skimmed milk and one-third cereal water for four days, and then cereal water and broth for two days, when the skimmed milk is resumed. If the skimmed milk is continued longer than four days, vomiting and diarrhœa result. Full milk or cream cannot be tolerated in any form. Few children are so intolerant of milk as this one.

After a severe summer diarrhœa it often requires months before the child can take the usual strength of milk. Every fall we have a few cases at the outpatient service of the Babies' Hospital of infants who cannot be given milk at all until early in the winter. These children are fed on animal broths, gruels, scraped beef, white of egg, etc.

Milk Idiosyncrasy.—These cases are extremely rare. I have seen but two. The first was a healthy girl nursed by the mother until she was five months old. The mother wished to have the baby on the bottle once a day so as to relieve her of the close confinement. She was given a milk food preparation which was promptly vomited. In a few days another milk food was tried and promptly vomited, producing nausea and prostration which lasted for a day. The mother then came to me with her story, and a weak milk mixture was tried with such disastrous results that we desisted from further attempts at artificial feeding. When the child was seven months old a weak milk food was again tried with like results. Not until she was a year old could cow's milk be taken. The mother was assisted in her nursing by the use of barley-water and chicken broth mixture.

In the second case, bottle feeding was attempted one week after birth with such disastrous results that the child nearly lost her life. A very weak mixture was used—1. of fat, .5 proteid, and 4. of sugar. When three months of age a feeding of 2. of fat, .5 proteid and 4. sugar was given, with resulting nausea, vomiting, and prostration which continued during the remainder of the day, the wet nurse's milk not being retained. The child was exceedingly prostrated and presented the appearance of an infant with an acute gastro-intestinal infection. At the seventh month another milk feeding was attempted; this time 2.5 fat, .75 proteid, 6. of sugar was given. The child refused the food, however, and possibly two teaspoonfuls of the mixture were taken. She was nursed shortly after, all of which nursing was vomited in one hour and the remaining nursings of the day, three in number, were vomited with the exception of the last.

Nothing has been said concerning the milk used or its production. It is understood that the physician will always use the best milk on the market. Of late great advancement has been made in securing a better milk, for which the people and the profession at large have to thank the pediatrists of this country.

· **Apomorphine as a Hypnotic.**—Douglas points out that while, as is well known, a tenth of a grain of apomorphine injected subcutaneously will produce vomiting, a thirtieth of a grain similarly administered is a prompt and efficient hypnotic. In mild insomnia and in furious delirium it has been found to produce sleep within twenty-five minutes The sleep is refreshing and restful, and no disagreeable after-effects follow. There is said to be no possibility of a drug habit being formed, as it becomes again a vigorous emetic if the dose is increased. There are no cumulative effects. The drug is therefore a safe one, deserving a widespread use.—*The Hospital.*

THE CLINICAL ASPECTS OF ACUTE INTESTINAL OBSTRUCTION.*

By HOWARD LILIENTHAL, M.D.,
NEW YORK.

A topic of such great importance and general interest as the one to which I invite your attention this evening can hardly be discussed too thoroughly. In spite of the fact that the ground has been gone over by numerous speakers and writers, it is impossible to read a single paper or to hear the simple report of a case without seeing new aspects and finding oneself in unexplored country full of suggestions and possibilities. Because of the vastness of the subject, I shall confine myself to observations on its clinical side, not touching so much upon the etiology and pathology as upon the diagnosis and treatment of the conditions as they are found in practice; and I shall further limit myself to the discussion of the more acute varieties of intestinal obstruction in which relief is urgently demanded.

Death from obstruction of the bowels rarely if ever occurs as a result of the mere retention of feces, for numerous individuals have their regular evacuations as seldom as once a week, while instances of much longer habitual intervals between defecations are occasionally observed. On the contrary, symptoms of grave import appear almost immediately on the occurrence of acute obstruction, and unless relief is obtained the disease progresses to its fatal termination within ten days or less from its inception. The causes which contribute most to the mortality of this affection are three in number. First, the shock incident to the strangulation of a vital organ. And it must be recognized that in acute obstruction from any cause the condition of strangulation, or impediment to the circulation invariably exists at some point or points; and this is as true of ileus depending on mere fecal impaction as of the anatomical obstructions. It is the impaction or wedging of the mass tightly within the gut and not the stasis which does the harm. Secondly, there is sepsis from within the distended and congested gut even without the onset of peritonitis. Kocher has shown[1] that the distension above the obstruction causes damage of the intestinal wall, with the occurrence of little spots of ulceration and even gangrene, and that there is absorption of infectious material from within the injured viscera. The third contributing cause is, I feel sure from the observation of many cases, the embarrassment of the functions of the lungs and heart by the distension itself, with consequent exhaustion of the vital forces in an already weakened individual. Either of the first two causes may be fatal without the existence of the third.

Intestinal obstruction is certainly far from rare, though it does not seem common enough to give the average practitioner sufficient experience to enable him to recognize the gravity of the situation with the promptness which is usual in certain other important surgical diseases, notably appendicitis. On the contrary, it is decidedly rare for the surgeon to be called so early that there is the least doubt in his mind as to the advisability of immediate operative intervention.

A. Schreiber, in von Ziemssen's *Festschrift*,[2] tells us that one-third of all cases of intestinal obstruction in Germany get well without operation, but at the same time he says that the recoveries are probably from neuropathic ileus, not the true mechanical obstruction. Again, we are told that there are, according to statistics, 4,000 deaths a year from this cause in Germany alone. He rightly regards it as a misfortune that such a large proportion of disorders diagnosed as ileus get

* Read at a stated meeting of the New York Academy of Medicine, held May 2, 1901.

well without operation since it encourages dangerous delay in the genuine cases.

The increasing frequency of abdominal section for the relief of other conditions has undoubtedly been the cause of an increase in the number of cases of ileus; but while this form of the trouble is particularly serious, owing to the liability to multiple constrictions by bands and adhesions, it is, at the same time, apt to be early recognized and properly treated. A case which I recall is of interest. The patient was a young man, a student, who was sent to me by his brother, a physician, because of an acute non-perforative appendicitis. There was free fluid in the peritoneal cavity at the time of the section. At the end of three weeks he was discharged from the hospital apparently well, but two weeks later was attacked by severe abdominal pain with vomiting, the symptoms becoming greatly aggravated after the administration of calomel, which did not act. His brother at once diagnosed acute obstruction, and I operated again within twenty hours of the onset. A coil of about eighteen inches of ileum had been constricted at both ends by an adhesion which bound them together in the form of a volvulus. The gut was extremely tense, and its walls were thickened by inflammation, but there was very little distension above this involved coil. Reduction was followed by prompt recovery. Had the former operation not indicated pretty clearly the diagnosis in this case, I believe that irreparable harm would have resulted on account of delay and further attempts at a cure with the help of catharsis. The violence of the symptoms and the appearance of the bowel at the time of operation indicated that a few hours more would have rendered the condition an almost hopeless one. A more uncommon form of postoperative obstruction is reported by Rehn,[3] the disturbance appearing four months after laparotomy for pyosalpinx. Forty centimeters of gangrenous gut had to be resected on account of an obturation by a tightly rolled gauze compress. Rehn thought that this object had probably been left in the abdomen at the first operation, and that it had subsequently ulcerated into the intestinal lumen, but he could not be certain that it had not been swallowed. Recognizing the actual danger of obstruction from these secondary adhesions all diligence should be exercised to prevent this accident. The intestine should be handed little and with great gentleness, and we should avoid, if we can, drainage by irritating substances.

Deaver, in a paper read before the Cleveland Medical Society[4] calls attention to the fact that appendicitis is often mistaken for intestinal obstruction and believes that the employment of opium is mainly responsible for this error. Nowadays, when the operation for appendicitis is so common, it is my experience that the converse of this mistake is more often encountered. In either case operation is demanded, the only question being as to the location of the incision.

I am convinced, however, that true ileus is often due to appendicitis. I do not refer to the bands left over from previous attacks, but to the coexistence of both acute conditions. It has been my fortune to operate in several of these cases and I can testify to their seriousness. In several instances the appendix had been drawn over to the left side of the abdomen by adhesions to the small intestine, with kinking and complete obstruction. The early occurrence of fever or other signs of sepsis, together with the discovery of a very sensitive place in the abdomen, should make the diagnosis of appendicitis probable even in the presence of ileus.

Before this audience it is scarcely necessary to describe or even enumerate the various forms of intestinal obstruction, though it may not be amiss to remind you of one or two points in the diagnosis of the condition. Tight strangulation in the small intestine occurring suddenly is accompanied by intense colicky pain, with nausea and vomiting, the ejecton of the stomach contents being often violent or projectile. Collapse comes on early. An enema given for diagnostic purposes will indicate by the quantity of water which can be retained that the trouble is not in the colon.

It may be necessary to empty the large intestine by enema before applying this test. An adult colon will hold from two to four quarts of water. The nearer the stomach the strangulation the more urgent is the need for speedy relief. A strangulation in the large intestine is not immediately accompanied by such violent vomiting, but there are tenesmus and griping pain with the discharge of mucus and, if there is intussusception, of blood or bloody mucus. It should not, however, be overlooked that in elderly individuals constricting neoplasms of the colon are far from rare and that acute obstructive symptoms from this cause with the passage of blood by the anus may simulate intussusception. Hiccough and the frequent regurgitation of intestinal fluids without nausea are common in the later stages of ileus and should be regarded as particularly ominous. Volvulus of the sigmoid with the constriction of the loop in the left iliac region may simulate a lesion in the right side of the abdomen because the most distended portion of the loop may occupy this position. In volvulus the loop distends very rapidly and to a far greater degree than the intestine above it, for the reason that its contents are actually imprisoned while the gut above has a partial vent through the stomach. This distended coil is the first to be paralyzed and will show no peristalsis, while the intestine above is still active.

In administering an enema careful observation is necessary in order that the expulsion of flatus be not overlooked or misinterpreted. It has not infrequently happened that air introduced with the enema has been expelled afterward by the patient and that the nurse has reported the passage of flatus. Air may also enter the rectum on the insertion of a tube unconnected with the syringe while the body of the patient is in the partially inverted posture, on the same principle which causes the ballooning of the gut during proctoscopy or of the vagina during examination in the Sims position. It is, therefore, recommended that the administration of enemata be superintended by the physician himself. The passage of foul gas is an indication that the complete obstruction has been overcome and is of far greater moment than the appearance of feces. In the chronic or partial obstructions which do not come strictly within the field of this essay griping pains with frequent nausea are the cardinal symptoms, together with visible coils of distended gut showing peristaltic action which is increased by abdominal palpation. A history pointing to chronic trouble obtained at the bedside of one suffering from an acute attack is of great importance in diagnosis and in the outlining of treatment as well.

It should be possible to make a working diagnosis of acute ileus without the appearance of marked distension and without the discovery of a distinct mass or tumor in the abdomen.

Fecal vomiting is such a late sign and of such a grave prognostic import that to wait for this symptom practically dooms the patient. Irving Snow[5] gives the history of a case in which even this symptom was treated by methods other than surgical because of temporary relief following enemata. The patient was a little boy three years old who had received a contusion of the abdomen, but who seemed at first

to have suffered no serious injury therefrom. His bowels had moved in an apparently normal manner, but three days after the accident he began to vomit incessantly and to complain bitterly of great agony in the abdomen. He was first seen by the reporter on the sixth day of the illness and on that day there was fecal vomiting. Injections caused intensification of the abdominal pain, but later there was a passage with little fecal matter and considerable gas. The distension subsided somewhat, but the stercoraceous vomiting continued. The second day after this peristalsis was visible and tympanites recurred. Two days later the fecal vomiting reappeared and an olive oil injection was given. It was followed by another small stool and flatus. Death came, without operation, on the twelfth day of the illness and autopsy revealed a strangulation by a Meckel's diverticulum. Oil, probably introduced by the enemata, was found in the intestine above the constriction. Snow says that the entire absence of tumor, induration, or tenderness made the diagnosis of intestinal obstruction improbable, and it was not made until the post mortem revealed the true state of affairs. Here we have to do with what amounted to a series of acute obstructions with intervening periods of partial relief. It illustrates the occasionally treacherous character of the apparent improvement noted after the employment of therapy other than operative. In discussing this case Christopher related the history of a recurrent intussusception operated upon with success by Henrotin. While the abdomen was open an attempt was made to effect reduction under the eye by means of rectal insufflation with air. The intestine below the strangulation became stretched to such a degree that it was evidently in danger of bursting should any greater strain be put upon it, but the intussusception was not in the slightest degree affected.

Sudden abdominal cramp-like pain with vomiting and no fever should be treated by an enema and, in the adult, by a *small* dose of morphine (Treves).[8] If permanent relief does not follow, the case becomes a very suspicious one, and, taking everything into consideration, will probably be safer with operation than without it. The progress of the symptoms will indicate the degree of urgency, but a further exhibition of opiates or the employment of cathartics will probably add elements of danger. This is, of course, a general rule to which there are a few exceptions. For example, if the patient is known to be habitually constipated and has not had an evacuation for some days, further attempts to empty the colon by means of various enemata may be considered proper. If the large intestine is empty, however, and the enemata do not bring away gas, we have probably to deal with an obstruction. Ischuria and great dryness of the mouth are of diagnostic value.

The medical treatment of intestinal obstruction of the acute kind is safe until the diagnosis is made, but no longer. By this I do not mean that an exact knowledge of the variety of obstruction present is necessary, but simply that the case should be recognized as one of acute ileus; after this the earlier the disease is treated by operation the better are the chances for recovery. Treves[8], Kocher[1], Gibson,[3] Maylard,[5] and many other surgical writers agree upon this point and have brought important statistics to bear upon it. Yet every year some new medical treatment for this eminently surgical disease is exploited. It is certainly conceivable and probably true that in volvulus and intussusception of recent formation, in which no adhesions exist, the stopping of intestinal motion may prevent further entanglement and will, perhaps, help the parts to return to their natural positions. Treves[8] points this out very clearly and gives as an additional reason for the administration of small doses of morphine the fact that the condition of shock is greatly reduced thereby. However, he fully realizes the disadvantages of continued treatment with this drug, especially on account of the dangerous masking of the symptoms. Atropine has also been highly recommended, but it increases the dryness of the mouth, always a distressing symptom, and I would add that if the drug is to be used in considerable doses, it is very apt to cause delirium, which it may be difficult to distinguish from that due to sepsis.

Some interesting recoveries following the employment of atropine have been recently reported. Batsch[9] has made use of this form of treatment in a number of cases. A woman twenty-eight years old, after confinement with instrumental delivery, had the symptoms of acute obstruction of the bowels with great distension and the vomiting of greenish-yellow masses. There was no fever and neither stool nor flatus. On the morning of the third day 2 mg. of atropine were administered, but in the evening there had been no relief and the patient went into collapse. A dose of 5 mg. was then injected and the patient was delirious all night, but the following morning considerable gas was expelled and recovery took place after another injection of 5 mg. The same author reported three later cases. A woman aged sixty, with obstructing symptoms for eight days, and two days of fecal vomiting, received 2 mg. of atropine morning and evening without avail. She was then prepared for operation, but was first given 5 mg. atropine, and after sleeping had a large soft stool. Recovery took place without operation. A man thirty-five years old had a sudden abdominal pain in the morning and stercoraceous vomiting by evening. The usual methods of relief were tried and the next morning he received 5 mg. of atropine. There was immediate relief of the symptoms with movements and the passage of gas. A woman of forty-five had obstipation with severe pain and vomiting. Atropine 5 mg. was administered for two days hypodermically with subjective improvement. Then fecal vomiting occurred and an operation was performed. A loop of intestine was found strangulated in the pelvis by a parametric band. The patient recovered and Batsch believed that the atropine had something to do with the fact that the loop of intestine had not become gangrenous. Marcinowski,[10] Ostermaier,[11] and others report similar experiences.

The drug seems to be recommended for two divergent reasons; first as an antispasmodic in strangulation by mechanical agencies, and second as a tonic in paralytic obstruction. I have had occasion to employ this treatment in one case on which I had operated on March 12th of this year. The patient had acute obstruction with peritonitis due to numerous bands following an appendicitis, which had not been operated upon. The bands were relieved, but the peritonitis continued, and the obstruction incident to that disease coming on, atropine was given to the verge of delirium, but without avail. My impression of this treatment is that it should be used, if at all, in those cases of ileus which are, in reality, exacerbations of chronic obstruction, to tide over the immediate emergency and prepare the patient for a radical operation at a future time; or, as one might say, in an interval. At any rate, I question the propriety of the employment of any treatment other than surgical when there has been stercoraceous vomiting. All the cases which I have observed in which this symptom had existed, showed on operation conditions

which it is inconceivable could have been relieved by other than mechanical means.

From the pen of E. Vidal[12] comes a surprising suggestion. He believes that there are probably antitoxic substances in the healthy intestinal wall which, if introduced into the system of an animal suffering from sepsis, due to absorption from the bowel, may counteract the effect of such absorption, even, perhaps, in cases of intestinal obstruction. He has made extracts with serum and with glycerin of the macerated mucous membrane of the gut of the pig, and has apparently found by experiment that in animals it acted as a direct antitoxin. Two trials with this form of therapy in the human subject were of doubtful value, but Vidal intends to carry his researches further.

It appears to me that if we are to expect anything at all from the animal extracts, their application should be strictly limited to those cases in which operation has already been performed, but in which the symptoms have not subsided, and the outlook remains grave. It should never supplant surgery.

Enemata in the attempted reduction of a suspected intussusception may be at first permitted. Little should be hoped for, however, unless that portion of the colon below the splenic flexure is alone involved, and the invagination is one in which the intussusceptum, or inner tube, is composed of bowel normally situated *above* the constriction. In reversed intessusception, enemata must obviously fail to reduce, and the diagnosis of this type of the trouble is impossible.

As to electricity and massage in acute cases, the serious manner in which these proceedings are recommended by a few recent writers would be actually laughable did it not mean that some practitioners will undoubtedly use them with probable tragic results. If an obstruction other than an obvious fecal impaction or obturation by a foreign body should be treated by massage or kneading of the abdomen, the danger of directly causing a perforation would be so great that a cure would have to be ascribed purely to good fortune, and this very cure should be deplored because of the pernicious example.

To illustrate the operative treatment of what might be called non-surgical obstruction, I will refer to J. Lewtas,[13] who cites the case of a patient who was operated upon twice within seven months, the condition found being in each instance a spastic contraction of about six inches of intestine, the affected part being no larger than a lead pencil. Above the contraction the gut was distended, as is usual in ileus. The treatment consisted in forcing the mass above the spasm through the contracted part. The patient recovered promptly after each operation. The trouble could not have been diagnosed without exploration.

From the 12th of August, 1893, up to the present time, I have operated upon thirty-four patients for intestinal obstruction. With the exception of four of these, acute ileus existed at the time of the operation, and the individuals were, in nearly every instance, in poor condition. There were six cases of intussusception, five being acute, with two deaths; four of volvulus, with three deaths; eight cases of constricting tumors of the colon, including the cœcum and the sigmoid, of which six were in the stage of acute obstruction, with two deaths. Obstructions due to appendicitis, which had not been operated upon, existed in four cases and all the patients died. Obstruction after the operation for appendicitis, due to adhesions, existed—two cases, with one death. There were two patients with intestinal obstruction in whom adhesions were found about the ascending colon, but no diagnosis was made; both died, and there was no autopsy. There were three cases of multiple adhesions due to old peritonitis, with three deaths. A case of complete obturation by a gall stone terminated in recovery. A patient with strangulation of the small intestine through a slit in the mesentery, died. A child with an intestinal hernia, through a rent in his rectum, died. A woman with obstruction due to adhesions about an ectopic gestation recovered. A case of gangrene in a loop of intestine reduced from a femoral hernia resulted fatally.

The percentage of recoveries is, on the whole, encouraging (forty-one per cent.). Besides these, I have had the opportunity of directing the treatment of a number of other cases which were operated upon in my service.

From this experience, I have formed certain ideas concerning the operative treatment of acute ileus which, with your kind indulgence, I will submit. (The complete report of the work will form the subject of another paper.)

The stomach should be washed out before operating and, preferably, before beginning the administration of the anæsthetic.

In the most desperate cases no general anæsthetic should be employed.

A small incision should first be made in the right iliac region, and if it is at once obvious that the key to the difficulty is situated here the wound should be enlarged and the operation proceeded with; but if this exploration proves negative, a long median incision should immediately be made.

If a strangulation exists the patient must not leave the table until it has been relieved.

The possibility of the existence of more than one obstruction must be ever present.

Enterostomy or colostomy should be performed only when there is the greatest danger that the patient may die if the operation is prolonged. I would, however, make one exception to this rule, and that is in cases of acute ileus from chronic obstruction in the large intestine with enormous distension. Here it is best to perform colostomy as a means of temporary relief with the hope of something more radical in the future.

In making an artificial anus, one must be certain that the opening is *above* the occlusion. Gibson[7] directs attention to this axiomatic rule and cites cases in which the error was committed.

Gangrenous intestine should be at once resected.

When there is great distension of the small intestine a sufficient number of small incisions opposite the mesentery should be made for the purpose of evacuating as much as possible of the gaseous and liquid contents of the gut *before* searching for the obstruction. Treves[6] thinks that the mortality of the operation for the relief of ileus will be reduced fifty per cent. by the emptying of the gut, but he advises that this be done after the relief of the strangulation. Maylard[5] says that it should be done beforehand. Kocher[1] agrees with the latter opinion and points out that the greatest danger in ileus is in absorption from the gut.

About four years ago, before having heard of systematic enterotomy being performed by any other surgeon, I began treating the distended intestine in this manner, both in cases of true obstruction before searching for the lesion and in the distension of peritonitis, and I placed the method before the New York Surgical Society on October 12th, 1898, when it received considerable adverse criticism.[14] I have continued to practise this treatment in suitable cases and have remarked nothing but good which could be attributed to it. I have never noted a leak at the points of suture of the little openings.

There is rarely, if ever, any advantage to be gained

by the administration of cathartics after the strangulation has been relieved, and this is especially the case when there has been a copious discharge of intestinal contents through punctures or incisions.

I am convinced that exhaustion due to delay and the persistent employment of purgatives is to blame for by far the majority of deaths which have come under my observation.

Surgery and surgery alone can logically promise relief in acute intestinal obstruction. The fear of operation, unreasoning as it is, must answer for many an opportunity missed, many a life lost. The time is short during which even operative measures will be of avail, and the hours are precious. Exploration risks little, but delay may render surgery unavailing. It is a fact admitted by the most sanguine advocates of the medical treatment that there are, unquestionably, many causes of obstruction which from their anatomical nature render anything short of operation valueless, and the only reason which can be given for procrastination is in the hope that the particular case in hand may prove to be one of those curable by other means.

When a patient has recovered after internal medication, or massage and electricity, it is certainly illogical to jump at the conclusion that an operation would have had a less fortunate result. Every recovery without surgery signifies that the disease was not a surgical one; while practically every death after operation means that medicine has failed and that surgery has finally been invoked to make the best of a bad case.

REMARKS ON THE SCIENTIST, THE PRACTITIONER, AND THE ANTITOXIN TREATMENT OF DIPHTHERIA.

By ADOLPH RUPP, M. D.,
NEW YORK.

The Scientist and the Practitioner.—The object of this article is to review and criticise some frequently repeated opinions on the antitoxin treatment of diphtheria which appear from time to time in lay and medical journals, besides some opinions that have reached me from various sources through letters written by medical men. Besides being of some historical interest, the article may be helpful by stimulating reflection, and possibly, it is hoped by the writer, will contribute a little toward a better knowledge of the facts that are subjects of assertion, contribution, and argument.

Antitoxin was discovered, tested, and proposed as a remedy for diphtheria by scientists, Behring and Roux. Originally it was claimed that antitoxin was as harmless as normal or physiological salt-solution; and, furthermore, if the remedy were applied within the first or second day of the disease, the mortality rate of the disease would be about five per cent. This was an ideal consummation devoutly wished for, and the remedy was adopted with enthusiastic avidity by a very large majority of influential clinicians, and received the ready financial support of philanthropists and the state. Very soon, too, indifference, and a lively opposition toward this new treatment made itself felt. The opposition is composed of eminent clinical teachers and scientists, and a considerable number of practitioners, all in good standing.

In passing judgment on the merits and demerits of the antitoxin treatment of diphtheria, and the discussion thereon, the particular work of the scientist should be distinguished from the work and functions of the practitioner. This is oftener taken for granted than borne in mind and acted on. As a social unit the medical practitioner is more closely bound to his fellow-beings, and is of much more immediate importance to them, than the scientist is or needs be. The practitioner treats patients, and is thus called on to solve problems that are particular and concrete, and which never as such became a part of the special and specific calculations the scientist or laboratory worker is occupied with. The scientist or laboratory worker is busied with set problems, inspired by abstractions, and guided by pre-arranged experiments. The net results that emanate from the scientists' observations, judgments, and representations often become necessaries for the practitioner to utilize in unraveling the particular disease complexes of individual patients. First, last, and all the time, the practitioner deals with individual patients, and not with clear-cut disease conceptions or entities only.

Like the scientist the practitioner, too, must theorize, but he starts from problems with the presentation of which he has nothing to do. In our day the physician and surgeon, as a rule, are not scientists. At their best they translate scientific realizations into practical possible utilities. Unlike the practitioner, the scientist does not fix his attention on the anarchy of disease as it exists in individual patients; but he busies himself with disease conceptions and the various biological phenomena inside and outside of bodies which give his conceptions a local habitation and a name. The scientist is the practical idealist. The practitioner the utilitarian realist. The former is no idle or fanciful dreamer, nor is the latter a mere crass empiric, who lives only from hand to mouth. In our day a true practitioner must be able to appreciate and put to good uses the well-established teachings of the scientist. In doing this he places confidence in the senses and the intellect of the scientist; but this faith is limited and kept alive by the activities of his own senses and intellect. Nor is this all. The inexpert common sense of the laity—men, women, and children—must be reckoned with to complete the circle of a happy realization of matured fact. The clients of the practitioner have sensitive emotions and wills of their own. These must be dealt with by the practitioner, and they are quantities and qualities altogether foreign to the subjects on which the scientist works. And on these accounts, in many senses, the practitioner, as such, will do wisely not to forget Sydney Smith's advice: "We should be careful how we squeeze out of human life more ecstacy and paroxysm than it can well afford."

Opinions for and Against the Antitoxin Treatment of Diphtheria.—Much has been said by all sorts of men and women about the blessings and utilities of the antitoxin treatment of diphtheria. Biological scientists like Prof. E. Haeckel, who know diphtheria and what antitoxin has done for it only from what they have heard others say, have pronounced in its favor. Universsity presidents and writers on the progress of culture, who are credited with omniscience, have rated the remedy very highly, and singled it out as illustrating the progress of science and human

achievement. Text-book writers and some clinical teachers have allowed their enthusiasm for the remedy such unbounded swing as to give the appearance that no doubt as to its efficacy (of the antitoxin treatment of diphtheria) exists. And Prof. William Oster of Johns Hopkins University, with considerable feeling and a self-satisfied sort of tact has printed the following pronouncement in the New York Sunday *Sun* (February 3, 1901): "Strange as it may seem, much opposition arose to this new method of treatment (serum-therapy), not alone from the lay portions of the community, but even from the ranks of the profession itself. The opposition was due, in part, to misconceptions of the principles involved in the new doctrine, and in part to the falsely philanthropic prejudices of the pseudo-scientific sections of both parties." This pronouncement is as unfair as it is unreal. It is simple cajolery on the one hand, and a déceptive diagnosis on the other. Grave mistakes for a serious professor to fall into! Especially so when writing in a lay journal. It is, or ought to be, a well-known fact that many highly respectable professional men, professors as well as busy practitioners, who oppose not serum-therapy as such, but the contentions asserted in its favor, have a fair and true conception of the principles involved in the new treatment. Many men who oppose the present antitoxin treatment of diphtheria are also opponents of the whims of the antivivisectionists. But why should the Hopkins professors say that Kassowitz, Ebstein, Winters, Herman, and many others do not understand the theoretical principles involved? Are the following words written to me by a New York pædiatric professor full to the brim of a comprehension of the principles of serum-therapy? The professor says: "Personally I think antitoxin has done everything for diphtheria. Every one in private practice must admit this. The results and practice in hospitals also show marvelous results in services by men whose work is of the first order." My friend is enthusiastic, but not more so than Prof. Osler in his article in the New York *Sun*, and his statement of the case is about as true to the facts. If such strong statements could be established by everyday and historical experiences, then all opposition to them would be nothing less than criminal perversity. But there is much on the scientific side that must first be settled before such statements can be called well founded scientifically. And there are men of the first order, who stand at the head of hospitals, who have turned an indifferent ear to the claims of enthusiastic believers, and others who have opposed them and continue doing so, and it is difficult not to be tempted to doubt the fair-mindedness of a man who will assert that all who are in private practice must admit that antitoxin has done everything for diphtheria.

By way of rebuttal, I shall begin by quoting from the letter of a young physician who has just finished a year's service at the Willard Parker Hospital. The doctor says he knows diphtheria only as he has seen it at that hospital, and under antitoxin colors. He writes, "I may say, after one year's service and observation at the Willard Parker Hospital, I am fully convinced of the utter worthlessness of the antitoxin treatment of diphtheria, and that its use is almost inhuman." Why inhuman? Because he found the cases there treated did badly. He also told me orally, what others have said elsewhere, that the cases treated with 1000-unit doses did better than those that had been given larger, 4000-unit, doses. This young physician did not enter the Willard Parker Hospital prejudiced against the new remedy. His negative convictions grew as his observations increased. Neither is he blind to the character of the cases that are sent to the Willard Parker Hospital. He is ready to make allowances for the seamy side of the run of cases there. It should not be overlooked that the doctor was with the cases he studied day and night, and not for a few minutes at a time once in twenty-four hours. His is not the only conviction that has taken on negative coloring at the Willard Parker Hospital.

Dr. Horace Manders, who cannot be accused of being prejudiced against or of misconceiving the principles of the new treatment of diphtheria, says in his book ("Ferment Treatment of Cancer and Tuberculosis," London, pp. 59-60): "It has been said that nothing very much is to be gained by this treatment either in mild or in very severe cases, and there may be some truth in this as regards the former; but I am inclined to think that such severe cases run their course very rapidly, and that the period in which antitoxin treatment would have any power is exceedingly limited and probably gone before it is attempted; again these fulminating cases have no doubt been invaded by a far greater dose than the so-called lethal dose." The disease distinctions made in this paragraph fit the therapeutical limitations taken into account, and more or less ease and satisfy the doubts of at least some practitioners. Such disease differences and therapeutical limitations are rarely dwelt on by "believing enthusiasts," as Osler terms men like my pædiatric friend quoted above. And it is for the disease differences and the therapeutical limitations that many of us who doubt are looking in order that we may be able to prognosticate our cases rationally on a scientific basis, when remedies are of no avail, whether those remedies belong to the "new treatment," or to the old human empirical kind. Diphtheria as a disease conception, has always been one of great latitude in so far as the question of severity and mortality is concerned, and with the appearance of the Klebs-Löffler bacillus on the scene its horizon was not narrowed but considerably widened. The bacillus is claimed by scientists as being, next to the tetanus bacillus, the most virulent that afflicts us. And yet scientists must admit that it is rather a capricious pest, because its virulency varies like the mortality differences of epidemics vary from the greatest benignancy to appalling virulency. For these natural variations, scientists, of course, are not to be blamed. Blame, however, attaches to keeping the fact in the background as though it were not of first rate importance. When the bacillus, for reasons that are still unknown, is tame its toxin is also tame, and the disease it induces in a susceptible individual is also tame. Furthermore, the clinical question of individual susceptibility is also a (clinically) immediate unknown quantity. What have we, even from present day scientific knowledge in connection with clinical empiricism, to expect in the way of curing diphtheria with antitoxin—a remedy the strength of which is measurably fugacious? Nothing but possibilities, and those quite uncertain. Let me quote another writer, J. Pierce Brown, M.B., L. R. C. P. E., who has seen diptheria as a general practitioner, and who is not unfamiliar with the disease from a specialist's point of view, and who says: "Toxins and antitoxins monopolize the attention of the medical world, and yet the exact status of the one and of the other in regard to propagation and prevention of disease it may take another half century to fully and absolutely define." (Said in the preface of his excellent treatise on Diseases of the Nose and Throat.) Such are some of the characteristic opinions for and against the treatment of diptheria with antitoxin at the present time.

The antitoxin question, as a therapeutical and a professional question, has nothing to do with prejudices pure and simple against antitoxin or serum. They are tried, and they are judged. And trying and

judging is a complex psychological problem, not of the individual only, but also of the crowd. The majorities of the day are not stable quantities. Minorities of to-day may be the majorities of to-morrow. The tide is turned by facts or supposed facts. We all want facts, and the secret of their relation and interrelationship.

Antitoxin began a glorious and promising career with what are, from present-day standards, comparatively small doses. A Health Board medico told me the other day that no curative effects can be hoped for from 1,000-unit doses. Now, "enthusiastic believers" give 60,000 units in just such cases where formerly 6,000 units used to accomplish the desired effect. Dosages now vary, not so much according to any certain or fixed standard developed by disease processes in the patient, and made evident by clinical phenomena, but rather according to the subjective ideal of the administration and what constitutes scientific necessities and demands. Uncertainties of bacterial virulency and uncertainties of toxic infection have as much to do with the synthesis of these ideal and arbitrary demands and necessities as the uncertainties of individual immunity have. Only in the laboratory everything is fixed, measured, and certain, and these laboratory factors are beyond question and doubt. But the certainties and assurances of the laboratory become in the human body probabilities at best, and often only problematical possibilities. Antitoxin and the philosophy of the scientists in its favor as applied to the treatment of diphtheria in human beings, is practically a rapidly vanishing possibility, and for the following reasons:

1. It is now almost generally admitted that the diphtheria antitoxin antagonizes only the diphtheria toxin; and

2. It is now almost generally admitted that the amount of toxin in a person suffering from diphtheria is an unknown quantity, and,

3. It is now almost generally admitted that the phenomena of diphtheria in the (clinical) sense are induced by bacteria and their toxins other than the Klebs-Loeffler bacillus, and

4. It is a demonstrated fact that many cases of clinical diphtheria are not specifically Klebs-Loeffler in character, and that a great many Klebs-Loeffler diphtherias are barren of all clinical evidences of diphtheria; therefore,

5. It may be asserted that on so-called scientific and clinical grounds (the uncertainties of individual resistence in the human subject, the unknown quantity of the disease toxin, the known diminishing quantity and quality in the antitoxic serum, and the arbitrary dosage given by different administrators), as well as for clinical reasons (the impossibility of giving the remedy early enough and before the toxin can do its harm, for antitoxin is powerless against damage already wrought), that antitoxin is practically a remedy of very limited utility, and that the enthusiastic believer aims his variously loaded syringe at a vanishing possibility.

A Case of Small White Kidney.—N. H. Brazil reports a fatal case in a boy of fifteen years. Clinically, the most noteworthy feature was the combination of œdema, pallor, and highly albuminous urine, characteristic of the large white kidney, with the cardiac hypertrophy and high tension pulse associated with the small red one. Pathologically, the case is of interest, as the author has been able to find only one other entirely unequivocal instance recorded of small white kidney.—*The Medical Chronicle.*

On the Treatment of Bright's Disease.—James Tyson believes that the tendency with all of us is to do too much in the way of treatment. The treatment of acute Bright's disease is most easily disposed of, the measures including especially absolute rest and depletion by purgatives, and occasionally by local blood-letting favored by warmth and moisture. Not so easy is the treatment of chronic Bright's. This disease is not inflammatory in any sense. The kidney is far more frequently anæmic than hyperæmic. One of three predominating local conditions exists. Either the tubules of the kidney are more or less choked with their desquamated, degenerated epithelium, which distends them and compresses the blood-vessels around and between them, cutting off their nourishment; or they are already destroyed and replaced by connective tissue, or a combination of these two conditions exists. The result is that secretion is interfered with and toxic matters accumulate in the blood. Nature, fortunately, always tries to restore her damaged organs and impaired functions, and we must help her as far as possible. The kidneys must have rest, hence the diet, including drink, must be properly selected. Proteid foods should be restricted, the degree being dependent on the severity of the case. Rice, potato, the various starches, and white bread with butter are perfectly allowable. When digestion is good, there may be added peas, beans, spinach, asparagus, and the like, as well as fruits in liberal quantities. Fats are allowable when they can be digested. In bad cases, all meats, even poultry and fish, must be forbidden. In mild cases, they should be restricted. The composition of poultry and fish is the same as that of red meats, the only difference being in the smaller amount of red blood in the white meats. A fatty and farinaceous diet, with vegetables and milk, is sufficient for health. Beef tea, bouillon, and beef extracts should not be used. Diluted milk is better than skim milk. Alcohol, strong wines, and malt liquors are disallowed. It is doubtful if light wines diluted with water are harmful. The functions of the skin and bowels should be promoted. Warm clothing, warm seasons, and warm climate are advisable. Alkaline mineral waters and solutions of alkalies are beneficial. The frequent use of the vapor bath has met with the happiest results. The author knows of no drugs which directly reduce an albuminuria. Hard work and violent exercise are harmful. Massage is valuable. Iodide of potassium should be tried in cases of contracted kidney. It should be given in small doses, from three to seven grains in adults, and discontinued when its specific toxic effect is produced.—*Therapeutic Monthly.*

One Hundred Successive Mastoid Operations.—E. W. Pyle reports a series of cases the main features of which are summed up as follows: The children, numerically four less than the adults, furnished three times as many acute cases; the adults three times as many chronic cases as the children; illustrating that the greater number of mastoid inflammations, sooner or later, demand surgical interference. Thirty-seven cases of subperiosteal accumulations and eleven adults giving evidences of having had cortical perforations, showed clearly the insufficient efforts nature had made to repair, as they had finally to succumb to operative necessities. Forty-five acute cases furnished thirty-three per cent. of the intracranial complications, mostly in children, and all the patients lived. Fifty-five chronic cases furnished sixty-six per cent. of the intracranial complications, and four patients died; illustrating the value of normal periosteums and the phagocytic property of the white corpuscles to resist pathogenic invasion, and specializing the importance of prophylactic treatment. Four cases were operated upon, perhaps too early and ill-advisedly, but beyond the possibility of a doubt ninety-six would have been vastly benefited by earlier operative procedure.—*Archives of Otology.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 Fifth Avenue.

New York, August 31, 1901.

THE ORGANIZATION OF NATIONAL MEDICAL ASSOCIATIONS.

At a time when the American Medical Association is contemplating a radical change of organization which may add to its efficiency as a medico-legislative body, the recent report of the Constitution Committee of the British Medical Association has a significant and suggestive interest. Both bodies are now very evidently too large and too unwieldy to serve their useful purposes. With such extensive membership scattered over wide sections of territory there is a need for concentration of energies along rigidly systematic lines.

In the parent society across the Atlantic such a necessity has been felt for a long time, and with our own organization an equal urgency for change is being equally manifested. The reform measures, whatever variety they may have in detail, must look towards despatch of business, concentration of collective energy, and descriminative representation of local and sectional interests. The accomplishment of such ends requires much hard work, and much deliberation and consultation, on the part of committees having the matter in charge.

In all national organizations representing large distributive and often conflicting interests much of the really good and useful work which should be performed goes for naught for want of proper arrangement, direction, and focalization.

A fundamental difficulty in all attempts at change of plan of work has been the separation of the executive and purely business interests of the organizations from the distinctly scientific ones. In the short time allotted to general meetings it has seemed to be impossible to reconcile these conflicting conditions. Occupying the greater part of a week each year it is not to the convenience of the delegates to have the sessions prolonged, as continued absence from home means additional loss of money. The real problem is the proper division of the time and not its extension.

The establishment of scientific sectional meetings in the American Society was an important innovation, and its immediate acceptance was an indication of its adaptability to the wants of the large majority of attendants. The formation of a governing council was also a proper move in the same direction.

With all this there is still need for many radical changes before the now ponderous medical body can carry out its higher and broader aims. All this is so well conceded that the means to the end are constantly open for discussion, as seen by the recent labors of the British committee. Its report is ripe with suggestion and broad in scope, and it may not be uninteresting to refer in detail to some of the points urged as applicable to our home organization. Although on a somewhat different plan from our own, it resembles it in sufficient particulars to enable parallel conditions to be met, especially such as pertain to the proper representation of local interests.

In some particulars the American Association has the advantage in the matter of disciplinary representation, as only members of recognized local societies are eligible as delegates. A proposed change in the constitution of the British organization is to make such requisite obligatory. This having been accomplished, the central purpose is to work only through elected delegates representing equally-apportioned membership in the local bodies. In this respect the plan of representation is similar to ours.

Regarding the purely executive functions of the British Association, it may be fairly said that they are more systematic, exact, and comprehensive than those which pertain to the American organization. Although there is a Central Council of Control, there are also two distinctly business branches of the British Association which have independent legislative powers on the different questions submitted to them. But such arrangement would hardly apply to the American system of organization, especially with the wide separation of districts to be represented and the difficulty of ready concentration.

What is more to the point of improved organization is the admirable division of extra committee work under special instruction from the council. In fact, by such means and through the regular standing committees all the real detail work of the Association is to be transacted, leaving for formal acceptance or rejection by the council or general session only such propositions as may be regularly recommended for final confirmation. By such means only can the complicated business of any national organization be properly disposed of and the requisite time saved for the important discussion of strictly scientific subjects. The methods of management of detail can be easily effected through the official organs, which, as weekly editions of official transactions, can keep the entire membership informed on all minor matters requiring elaborate preliminary reports.

THE SCIENCE OF CAMP SCAVENGING.

So much attention has been called within the past few years to the importance of flies as agents in the conveyance of certain diseases, that literature bearing on the subject, and especially practical suggestions for the destruction of the pestiferous insects will be welcomed from any quarter. Dr. L. O. Howard, some few months ago, published a pamphlet in which he showed that the musca domestica was probably responsible for a very large amount of sickness, and further advised that measures which he indicated should be adopted for its suppression. The amount of evil wrought by the dipterous insects in the Spanish-American war, in the campaign in the Philippines, and in the South African struggle,

is a question which would seem to be rapidly leaving the realm of conjecture and day by day to be approaching the region of established fact. Dr. Victor C. Vaughan and the other members of the Commission appointed to enquire into the causes of diseases and especially of typhoid fever in the United States army during the late war, expressed in their report their strong belief that flies were one of the dominating factors both in the origin and spread of enteric fever. Dr. M. A. Veeder, one of the first exponents of the theory in this country, wrote an article in the MEDICAL RECORD some two years ago, setting forth in the clearest possible manner this view of the matter.

Macrae and Haffkine, in India, came to the conclusion that flies should be looked upon in the light of poisonous agencies of the worst kind during cholera epidemics, and Dr. H. H. Tooth, speaking of his experience in the Transvaal campaign, declares his conviction that flies have played a leading role in disseminating typhoid fever among the British soldiers. Dissenters from the theory must allow at least that a case founded on strong circumstantial evidence has been brought against flies, so strong, indeed, that is not quite complete in all its links, yet sufficiently convincing to warrant the waging of a war for their suppression.

Dr. G. V. Poore, in *The Lancet*, May 18, while disclaiming any deep knowledge as an entomologist, gives some practical common-sense advice with regard to keeping military camps comparatively free from flies. He says that flies multiply at a prodigious rate, and given a temperature sufficiently high to hatch the eggs, their numbers are limited only by the amount of food available for them. Linnæus is credited with saying that three meat flies, by reason of their multiplication would eat a dead horse quicker than would a lion. According to Packard the house fly makes selection of horse dung by preference for ovidepositing, and as each female lays about 120 eggs, and the cycle of changes from egg to fly is completed in less than three weeks, it seems probable that a female fly might have over 25,000,000 descendants in the course of a summer. Other varieties of flies are said to multiply still more rapidly.

As flies multiply on and in organic refuse of every kind, it is obvious that the sooner such refuse is placed where it cannot serve for the feeding and hatching of flies, the more likely is the plague of these insects to be lessened. The most commonly available method for the bestowal of organic refuse is burial. But the egg-laying of flies in dead carcasses commences at the very instant of death, or even before death in the case of very enfeebled animals. It is obvious, therefore, that there must be no delay in the burial of organic refuse and that the burial of animals and excreta is quite as important as the burial of human beings. After a great battle it may not be possible to follow this advice, but nevertheless there can be no harm in insisting that the instant burial of all organic refuse must be the aim of those who are called upon to guard the public health, whether military or civil.

Dr. Poore urges the burial of faeces and organic refuse in shallow trenches well covered with earth, no particle of faeces or paper to be left uncovered. Thus there will be no offence to eye or nose, no putrefaction is possible, the faeces are beyond and reach of dipterous insects, and if there has been no delay in their collection and burial, they cannot have been used for ovideposition to any great extent, so that the soil will not become infested with "grubs." The ground beneath which the refuse is deposited should, when the work is done, have the appearance of a well-prepared garden bed, and will need a little attention until it is covered with herbage of some kind—grass, cabbage, cereals, onions, mustard and cress, lettuce, spinach, or what not. With a little care, in a hot climate, one may have a green covering of grass or of mustard and cress in a week, which will at least give off oxygen to the air, even if it do not serve as an anti-scorbutic diet for man and beast—a diet which may supply that something which is lacking in tinned and salted provisions.

In advising the immediate collection of all organic refuse and its instant covering with earth, Dr. Poore claims that he is making no new recommendation, but that in the Scriptures this method is advocated. That grand old sanitarian, Moses—who may be called the father of sanitary science—had had experience of a plague of flies in Africa, and was no novice in the matter of the management of camps. He found it necessary to be most explicit in his directions for the treatment of excreta. These directions are given in Deuteronomy XXIII, 12-14: and in the revised English version there is an interesting change in the passage. The old version runs thus:

"Thou shalt have a place also without the camp, whither thou shalt go forth abroad.

"And thou shalt have a paddle upon the weapon; and it shalt be when thou wilt ease thyself abroad thou shalt dig therewith and cover that which cometh from thee."

The new version says: "Thou shalt have a paddle among thy weapons," and as a variant for paddle gives "shovel" in the margin. The passage, therefore, means that a shovel for burying excreta immediately is a necessary implement in every camp.

Dr. Poore's suggestions for the disposal of excreta and camp refuse would appear to be both practical and effective, and should involve little or no more labor than is expended upon the present haphazard way of depositing the germ-bearing material in places adjacent to the camps, and providing a happy hunting and breeding ground for flies.

The fact has been borne upon the minds of the government and military authorities of this country and Great Britain that in military camps sanitary arrangements must be carefully supervised if a fearful mortality is to be avoided. There can be no doubt that defective sanitation—much of which was avoidable—has been the cause of death of thousands here and in South Africa. The question is whether experience will teach.

THE PREVENTION AND CURE OF TUBERCULOSIS

IN a recent communication to the *St. Louis Courier of Medicine*, Dr. Beverley Robinson of this city very truly says that "no problem before the medical profession to-day is of greater interest than that of the proper disposal of our consumptive patients." The vital question is of two-fold significance—how we can prevent the spread of the dire disease and how we can best care for the afflicted ones. In

spite of the now well recognized fact that tuberculosis is a limitedly communicable disease, the matter of greatest importance, as intimated by Dr. Robinson, is to lessen the susceptibility of certain individuals having hereditary predisposition. This is the point repeatedly taken by the MEDICAL RECORD in its effort to strike a middle ground between two extremes of opinion. The seed must have a proper soil. Without the latter, the tubercle bacillus is innocuous. If it were otherwise every other man, woman, and child would become infected. The bacillus in populous communities is widely disseminated and the susceptible individuals are the ready victims. While we strive to isolate the stricken victims in sanatoria, we guard in a great measure against the spread of the seed and at the same time help to cure the patient. But it can be easily seen that behind all this are the countless number of waiting victims who need only the opportunity of every-day infection.

Says Dr. Robinson: "Take the poor in our large cities and towns; are they not the ones most frequently affected, and for whose welfare we should be most concerned, since they are in much larger number? Let our legislatures, then, see to it that in the tenements the air supply is sufficient and good, let sunlight penetrate dark, ill-smelling rooms, let cleanliness be obligatory. Enforce proper oversight of food and water supply, and soon, very soon, tuberculosis will diminish greatly.

"Of course, tuberculous patients should not be permitted to expectorate on floors or carpets, either in their homes or in places of public resort; but neither should healthy people be permitted to indulge in an unseemly, barbarous habit of that sort. It is opposed to decency, it shocks the senses of all refined persons—that is enough. Let it be interdicted on this ground, but not because contagion may be rife in every sputum that becomes dried and wafted in the air. It seems to me that the former idea makes an appeal to every one who desires progress in refinement and civilization; the latter idea merely raises questions and antagonisms, and why? Because, when thoroughly sifted, the proof is often lacking to make it absolutely demonstrable.

"Now, then, should we build sanatoria throughout our land, equip them with every modern improvement, make a large outlay of private or public funds, only after a shorter or longer period of rest, nursing, medical care, to send back these same persons either cured, improved, stationary, or worse, to conditions and surroundings which are the source and origin, in my judgment, far more of the widespread pest of humanity than the *microbe* whose inoffensiveness is demonstrable when the causes which breed it and make it important cease to exist?"

The Relation of Nourishment to Sex Production.—M. Camille Flammarion communicates to the Paris edition of the *Herald* the results of some experiments in radiculture at the Juvisy Observatory. Experiments made with silkworms tended to show that those kept under dark-colored glass ate less than those kept under light-colored glass, and also that under the darker glass the percentage of males produced was greater than under light glass. M. Flammarion thinks that his experiments coincide with the theory that a preponderance of male births occurs when there is a diminution in the quantity and quality of nourishment, supposing that sex can be influenced by external circumstances at all.

News of the Week.

Physical Examination of Passengers at Honolulu.—After the appearance of the plague at Honolulu a rule was established that all Chinese arriving at that port should be subjected to a physical examination before being permitted to land. It is reported that the officials there have recently extended the order to embrace Japanese as well, and that several men and women of that nation, first cabin passengers on steamers touching at Honolulu, have been examined in spite of their energetic protests. The Japanese Government has taken cognizance of the matter, and has lodged a protest at Washington against this system of medical inspection at Hawaii, declaring that it is incompatible with friendly intercourse between the two peoples.

The Yellow Fever Experiments in Havana have resulted in a third death, that of Miss Clara Maas, an American nurse at Las Animas. She had previously been bitten several times by supposedly infected mosquitos, without result. Eight persons were inoculated in this series of experiments, but only six took the disease, so the mortality was 50 per cent. These experiments have been carried on by the Yellow Fever Board, and have had nothing to do with the tests of Dr. Caldas, who is making his own experiments with a man inoculated with his serum and subsequently bitten by infected mosquitos. The result in this case seems to have promptly and effectually disposed of the claims of Bellinzaghi and Caldas as to their serum. The man was taken ill about four days after being bitten by the infected mosquito, and the Yellow Fever Board, consisting of Drs. Havard, Gorgas, and Agramonte of the U. S. Army, and Finlay and Guitéras of Havana, have unanimously agreed that the disease is yellow fever. The work of Dr. Caldas is being merely supervised by the Yellow Fever Board, which refused to join in his tests, owing to the secrecy observed by him in regard to his work.

What Sanitary Science Has Done for the Country.—The Census Bureau has issued a bulletin giving the mortality statistics during the year 1900 in the states and territories and in the principal cities where accurate records are kept. The total number of deaths reported for the year was 1,039,094, as against 841,419 for 1890. There was a decrease in the general death rate in the registration area of 1.8 per 1,000 population, a decrease of almost 10 per cent. The average age at death in 1890 was 31.1 years; in 1900 it was 35.2 years.

A New Lamp for Phototherapy.—Dr. Sophus Bang, an assistant of Dr. Finsen in Copenhagen, has invented a special electric lamp, giving a feeble light, but extremely rich in chemical rays, for phototherapeutic uses. Dr. Bang uses metal instead of carbon poles. The bactericidal power of this lamp is said to be ten times that of the ordinary arc lamp hitherto employed by Finsen in the treatment of lupus and other affections.

Smallpox in New York State.—According to the mortality bulletin of the New York State Board of Health, for July, there were just 100 deaths from smallpox in the State during that month. Of this number eighty deaths were in this city, five in Yonkers, and fifteen in other parts of the State. Seventy-two of the deaths occurred at the smallpox hospital on North Brother Island.

The British Association for the Advancement of Science, better known simply as the "British Association," will meet this year in Glasgow on September 11–18. At the close of the meeting many of

the members will make a geological tour of the Highlands.

A Colorado Marriage Law.—A bill has been offered in the Colorado Legislature to regulate marriage in that State. If the measure becomes a law it will not be possible for any couple to marry until after having submitted to a medical examination, and having been certified as sound in mind and free from tuberculosis, cancer, syphilis, and some other of humanity's woes. The examinations will be conducted by a board of examiners, which is to sit ten days in each month, and any one marrying without a license based upon the board's clean bill of health will be subject to heavy penalties.

The Malaria Expedition in Africa.—A report has been received by the Liverpool School of Tropical Medicine from Major Ross, regarding the work of the malaria commission at Freetown, Sierra Leone. The purpose of the commission was to extirpate, as far as possible, the malarial mosquito, and to study the results of extirpation upon the prevalence of malaria. In his report Major Ross says that seventy-four men are constantly at work draining away the pools where anopheles breed. Within ten days after work was begun several of the worst streets in the town, formerly full of anopheles puddles, had been leveled and drained. Another gang of seven men, with carts, was engaged in destroying mosquito larvæ in water receptacles in the houses, and in carrying away tin cans, broken bottles, old buckets, etc., in which the insects breed. They were clearing about forty houses daily, and carried away about ten cartloads of old pots every day, of which about one-third formerly bred mosquitos. This was regarded, however, as only preliminary work, the greatest task being to dissipate the pools of water left in the dried-out beds of streams after the rainy season closes, and which are the most prolific of all hatching places for mosquitos.

A Hospital School.—Dr. John M. Dodson, of the Rush Medical College has established the Hospital School for Nurses and Delicate Children, in which experiments looking toward the mental and bodily improvement of deficient children by dietetic measures will be carried out. The experiments will begin early in October and will continue at least one year. The children will be divided into two groups. In each group of invalids will be one normal child. A test of the mental and physical powers of the children will be made at the beginning, and these tests repeated at regular intervals, so that data may be secured regarding the effect of certain foods on mind and body.

Tuberculosis Experiments.—Volunteer subjects of experiments to test the communicability of bovine tuberculosis to man are presenting themselves in all parts of the world, and if the question is not definitely settled within a very short time it will evidently not be through lack of suitable material.

Bogus Dental Degrees in Germany.—The authorities are about to prosecute some 250 men found to be practising dentistry under bogus diplomas in Germany. The government has heretofore spasmodically dealt with single cases, but it is difficult to convict, because it has been unable to prove fraud, especially when the accused avoided using the title of dentist. Many of these offenders obtained their false diplomas in this country, it is said, from certain members of the former Board of Dental Examiners in Illinois.

An Unauthorized Tuberculosis Experiment. A clergyman has been arrested in Liberty, N. Y., on complaint of the village Health Board, and held under bonds by the Grand Jury on a charge of violating the village health regulations. He owns an extensive piggery, and the cause for his arrest is the fact that he has been collecting the refuse from the tables of a sanatorium for consumptives and feeding the same to his swine.

Hydrophobia in Paris.—According to the *Herald*, the authorities of the Pasteur Institute in Paris have issued a warning regarding the ever-increasing number of cases of rabies in that city, and insist upon a vigorous application of the muzzling law. Professor Metchnikoff says that there are more stray dogs in Paris than in Constantinople, and severely reproaches the police for their neglect to apply the law, which gives them power to insist on a muzzle or a leash.

A Woman Health Inspector has been appointed by the Board of Health of Orange, N. J. Several women's clubs have urged the appointment of a woman inspector, intimating that the salary of such would be paid by them. The inspector is Mrs. Elizabeth M. Devine, and her official salary is one dollar per year.

A Tuberculosis Scare in London.—The London correspondent of the *New York Times* says that the latest tuberculosis scare in that city concerns the manufacture of a popular woolen fabric, largely worn in men's sporting clothes, and rough wear suits generally, which is made in little, ill-ventilated, single-room cabins, by peasants among whom consumption prevails. It is believed that the cloth sent from these huts is full of whatever bacteria are generated or developed in them.

The Latin-American Medical Congress.—The first congress, at which a permanent organization was effected, was held in January of the present year in Santiago de Chile. The second will be held in Buenos Ayres, April 3 to, 1904, at the same time as the fourth Pan-American Medical Congress. The committee on organization of the congress consists of Dr. Emilio R. Conti, *President;* Dr. Robert Wernicke, *Vice-President;* Dr. Gabriel Carrasco, *Treasurer*, and Drs. Gregorio Araoz Alfaro and Nicolás Repetto, *Secretaries*.

Smallpox Among the Winnebagoes.—An inspector sent to investigate the epidemic of smallpox among the Winnebago Indians in Wisconsin reports that the disease prevails to an unusual extent, there being over eighty cases in three towns occupied by them. The health officers are powerless to enforce isolation of the sick, and in consequence the disease is spreading widely.

An Isolation Hospital for Orange.—The authorities in Orange, South Orange, and West Orange, N. J., are discussing a plan for the erection of an isolation hospital for joint use of the three places in case of an outbreak of contagious disease.

Obituary Notes.—Dr. Alfred S. Dana of Yonkers, N. Y., was killed while attempting to drive across the Harlem Railroad tracks at Bronxville on August 22. He was a graduate of the Medical Department of Columbia University in 1874. Dr. C. J. Nordquist of Mount Vernon was killed on the same crossing several years ago.

Dr. Thomas J. Turner, Health Officer of Coldwater, Mich., died at Mackinac Island on August 20. He was a retired naval officer, having entered the navy in 1853, and was Fleet Surgeon on Admiral Farragut's ship *Hartford* at the battle of Mobile Bay. Later he served as Medical Director of the United States Navy until retired in 1882. At one time he was detailed by the Secretary of the Navy as Secretary of the National Health Board, and he also acted as the head of the Bureau of Hygiene.

Obituary.

THOMAS MASTERS MARKOE, M.D.,

NEW YORK

Dr. THOMAS M. MARKOE of this city died on Monday of this week at his summer home in East Hampton, L. I., at the ripe old age of eighty-two years.

Dr. Markoe was born in Philadelphia on Sept. 13, 1819. He was graduated in arts from Princeton College in 1836 and in medicine from the College of Physicians and Surgeons, this city, in 1841. For several years in his early career he was Professor of Anatomy in Castleton Medical College, Vt. In 1852 he accepted the chair of Pathological Anatomy in the medical department of the University of the City of New York, which he held until 1854. In 1860 he was elected adjunct Professor of Surgery in the Medical Department of Columbia University (College of Physicians and Surgeons), in 1872 he succeeded to the full chair, and in 1879, on its division, he became Professor of the Principles of Surgery. At the time of his death he was Emeritus Professor of Surgery in the same institution.

Dr. Markoe served in various capacities throughout the Civil War. At the outbreak of hostilities he was appointed by Governor Morgan a member of the special corps of volunteer surgeons, being stationed at Fortress Monroe. In 1862 he was one of the Board of Examiners of Contract Physicians and Surgeons, and in 1863 was Visiting Surgeon to the New York Soldiers' Depot. In 1864 he was ordered to Fredericksburg, and subsequently to other posts where he had active service in the field and brigade hospitals.

For nearly sixty years Dr. Markoe was a prominent and commanding figure in the medical life of this city and at the time of his death was among the last of a generation of practitioners whose names add luster to the medical history of New York. He was closely identified with the New York Hospital for over half a century. He entered there as an interne in 1839, before his graduation in medicine, was appointed curator of the pathological museum in 1842 and from 1852 to 1892 was in active service on the attending surgical staff. In 1892 he was retired at his urgent request, and was made a consulting surgeon. He early won success in private practice, although his fees for the first year, as he used to tell his pupils for their encouragement, amounted only to something like $92. A few years after graduation he became associated with Dr. Edward Delafield, remaining in partnership with him for sixteen years, and subsequently formed a partnership with Dr. Francis Delafield. In addition to his long connection with the New York Hospital, Dr. Markoe served at various periods as attending surgeon to the Nursery and Child's Hospital, the Mount Sinai, Bellevue, and Roosevelt Hospitals, and later as consulting surgeon to the Mount Sinai, Woman's, Roosevelt, Orthopædic, St. Mary's, Vassar, and Nursery and Child's Hospitals, and to the Northern Dispensary. He was also a member of the Academy of Medicine, the County Medical Society, the Pathological Society, the Surgical Society, and the Society for the Relief of Widows and Orphans of Medical Men, and of a number of clubs, and literary, artistic, and musical associations. He was the author of a very practical work on diseases of the bones, and of occasional journal articles, but he was not a prolific writer, devoting himself preferably to didactic and clinical teaching, in which he had few rivals in his day.

As a man, Dr. Markoe had a most charming personality; he was affable to strangers, devoted to his friends, and kind and considerate to all, high or low, with whom he came in contact, either professionally or in business relations. To his private pupils, of whom there was a long succession during his days of active teaching, he was always a friend and a counsellor, aiding them in every possible way in their pursuit of knowledge, and in their post-graduate career sympathizing with them in their trials and rejoicing in their triumphs. As an operator, he was conservative rather than brilliant, though by no means devoid of originality in his methods. Outside of his professional life he was a man of deep culture, a lover of books, a connoisseur of pictures, and a musician of no mean ability. He was a man of conscience and of devotion to duty, and one of those through whose lives the world is enriched and an example is set for succeeding generations. He gave two sons to the profession he loved so well, both of whom are practitioners in this city.

Correspondence.

FINLAY'S MOSQUITO THEORY BEFORE AND AFTER ITS OFFICIAL INVESTIGATION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In view of a remark in Dr. Reed's recent address, published in the issue of the MEDICAL RECORD for August 10th, stating that I might be said "to have disproved my own theory," I beg to recall the essential points of my mosquito theory of yellow-fever transmission, as it stood three years ago, before there had been any thought of having it *officially* or otherwise investigated. The readers of the MEDICAL RECORD will thus be in a position to determine whether it is likely that I should have been lured by erroneous experimental results to draw such accurate conclusions as mine must now be acknowledged to have been. I would also call attention to the fact that, while recording my earliest ideas on some particular points, Dr. Reed completely ignores several important modifications which I found it necessary to introduce by reason of accumulated experience with those very experiments which he now impugns, when he might easily have informed himself about those modifications by consulting the three or four articles which I have written and published in this journal since May, 1899.

The essential points referred to may be summed up in the form of propositions, as follows:

1. The Culex mosquito R. D. (C. tæniatus Meigen, C. elegans Ficalbi, Stegomyia tæniatus Theobald, but not the C fasciatus Fabr. for the C. mosquito has no white bands on its proboscis) is the particular species of gnat which I have always pointed out as the one by which yellow fever is normally transmitted in Havana.

2. Since 1898, I formulated the principle that, in order to account for the fact that only the C. mosquito appeared to be capable of transmitting yellow fever, it was necessary to consider that particular species as the only one (in this country) which had pathogenic susceptibility for the yellow-fever infection. The germs would multiply in the body of the insect and finally invade its salivary and venom glands, so that they would be discharged with the secretions of those glands along the track of the wound and into the capillary vessel entered by the sting when the insect attacked its next victim (see MEDICAL RECORD, May 27th, 1899).

3. I had satisfied myself, as a result of my long-continued experiments with contaminated mosquitos applied (one or two at a time) not later than from two to five days after the insects had bitten a patient with yellow fever, that it was useless to attempt to contaminate these mosquitos from mild cases. I concluded: (*a*) that this procedure, in the summer season, *sometimes* develops a mild attack, similar to some of the experimental cases recently elicited by the more perfect methods adopted by Dr Reed and his colleagues; (*b*) much oftener, however, (in the proportion of six or seven to one) the aforesaid procedure fails to develop any perceptible pathogenic effects, even though the subsequent histories of the inoculated persons had left no doubt in my mind but that most of them had thereby acquired a complete or a partial immunity, enabling them to withstand subsequently severe exposures to the yellow-fever infection, either without becoming themselves infected, or contracting only such mild forms as some experts are loth to recognize as genuine yellow fever.

4. Since 1891 I had been convinced, from a careful study of Melier's report on the St. Nazaire epidemic, that by extending the interval between the contamina-

tion of the mosquito and the inoculation of a non-immune to more days or weeks, instead of the two to five days' limit which I had adopted, I should run the risk of developing a severe or a fatal attack, such as I was particularly anxious to avoid (see MEDICAL RECORD, January 19, 1901).

5. In view of some belated cases of yellow fever which had come under my notice and were difficult to reconcile with the limit of thirty-five to forty days during which I had been able to keep my mosquitos alive, I was induced to suggest that the issue of an infected mosquito (developed from eggs which had traversed the infected cloaca) might, possibly, be also capable of reproducing the disease (see MEDICAL RECORD, May 25, 1899). The necessity for this additional factor, however, has now, in a great measure, disappeared since Dr. Carroll's success in keeping the infected mosquitos alive during periods of seventy and seventy-one days. It is, nevertheless, a point which deserves to be further investigated, notwithstanding the negative result in Dr. Reed's only trial, and also in one of my own.

Dr. Reed's persistence in discrediting my positive experimental results, as explained in Proposition 3 (*a*), is all the more extraordinary from the fact that the experiments made by his colleagues and himself, upon those lines, with mosquitos which had bitten a person with a *severe* or fatal form of the disease only a few days before the inoculation, have been very few in number, and all of them during the winter season. The influence of the season is being just now exemplified by the greater virulence of the attacks produced by inoculations which, in winter, under similar circumstances, would probably have been attended with mild results. Two unexpectedly severe cases, which ended fatally with black vomit, have thus occurred at the Experimental Station, and furnish a warning not to place too much reliance upon previous results obtained in a different season, and evidently justify my former reluctance to experiment, on my sole responsibility, with mosquitos, whose contamination had been allowed to reach its fullest development.

There are yet many important points to be accurately determined before any one of us can consider himself in a position to discredit the others' work.

CHARLES FINLAY, M. D.

HAVANA, August 20, 1901.

THE PROPAGATION OF YELLOW FEVER

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: While admitting the great value and interest of Dr. Reed's paper upon this subject, in a recent issue of the MEDICAL RECORD, his experiments ought to be verified by the careful work of others before his conclusions are unhesitatingly accepted, and sweeping changes made in our quarantine laws. Is the present theory that mosquitos are the sole agency in the transmission of yellow fever impregnable? The history of the successive investigations is not such as to inspire great confidence in any of the conclusions that have been reached. Confining ourselves to the work of our own Army and Navy Departments, we find that Surgeon-General Sternberg, after disproving the work of all previous investigators, announced the bacillus x to be the cause of yellow fever Surgeons Wasdin and Eddings of the Marine-Hospital Service, as the result of their experimental work in Cuba, stated unequivocally that "there exists no causal relationship between the bacillus x of Sternberg and this highly infectious disease." The true cause, according to them, is the organism discovered by Sanarelli, the B. icteroides and infection takes place by way of the respiratory tract. Dr. Reed of the Army Department, after experimenting upon two pigs, alleged that this particular organism was only a variety of the hog cholera bacillus, and that it was one of the secondary organisms which invade the body in the last hours of life, which, of course, the naval surgeons would not admit. And now Dr Reed cannot find the bacillus icteroides at all, either in the blood of the living or in the bodies of the dead. The result of his search for this organism in twenty-one cases during life and eleven autopsies was entirely negative. But the naval surgeons have yet to be heard from, and if we go further afield, we find already other investigators, such as Durham and Myers of the Liverpool School of Tropical Medicine —one of whom lost his life studying the disease in Brazil —challenging the theory of Dr. Reed. Where is the scientific certitude in all this that would compel us to change our views?

That the bite of a mosquito, by mechanically conveying disease germs from the sick to he well, is one of several modes of infection may readily be granted. As Manson observes, in connection with bubonic plague, "One can understand how lice, fleas, bugs, and perhaps flies, might act as carriers of the virus from person to person, inserting it with their bites. Yersin found that the flies in his Hong Kong laboratory died in great numbers, their bodies being crowded with the specific bacillus." Relapsing fever and other diseases may also be conveyed by insects, and perhaps eventually we shall find that smallpox, scarlet fever, etc., may be conveyed in the same manner. Indeed, in the writer's opinion, which, of course, is heterodox, other suctorial insects beside the mosquito are capable of conveying even the germs of malarial fever. We do not, then, dispute the assertion that the mosquito is one agent in the transmission of yellow fever; it is the claim that she is the sole agent, and that, if we can only guard ourselves from her bites, we have nothing to fear, that one stumbles against. In accordance with this theory, the connection between yellow fever and defective sanitation is denied. Why, then, do epidemics generally begin in the filthy streets of seaport towns? In a South American seaport, where the writer lived for a couple of years, cases of yellow fever were seen now and then; but though the place swarmed with mosquitos of every species under heaven, certainly of great variety, no epidemic occurred until some time after the outbreak of a political revolution. Several battalions of soldiers then came to the city for its defense, and were quartered in barracks where the sanitary arrangements were as bad as they could possibly be. Political prisoners were confined in cells beneath the city walls, and as they were never permitted to leave them for any purpose whatsoever, the stench became so abominable that everyone as far as possible kept away from the neighborhood. A severe epidemic of yellow fever soon broke out, and every day there were many deaths from this disease. Surely, in this instance, the connection between the epidemic of yellow fever and bad sanitary arrangements cannot be denied. There was some other factor beside the first yellow fever patient and the mosquito. On the other hand, it is puzzling to know that in the days when no defensive measures whatever were taken against mosquito bites, if yellow fever patients from an infected ship were disinfected and all fomites removed, they could be treated on shore in general hospitals with entire safety to others. Surely the wards of such hospitals contained mosquitos, the Culex fasciatus among the rest, and they bit infected patients, and the germs reached their proper development within them, and then they bit other people, just as it is claimed for their descendants now. How, then, did non-immunes, in contact with such patients, escape infection?

Until we are positively sure there is absolutely no other way by which the disease is spread, the necessity of dealing with the origin of the disease is surely as important as dealing with one mode of transmission. One of the hot-beds of yellow fever is Cucuta, in South America. The natives there assert that yellow fever was not known among them until some years ago, when two men, sick with the disease, came there from another part of the country and died. In accordance with Spanish custom, their bodies were interred in vaults for two years; at the end of that time, no one claiming the remains, they were disinterred and the bones scattered upon waste ground. Shortly afterward, an epidemic of yellow fever broke out, and since then the disease has always prevailed with more or less severity. This, to be sure, is only a "traveler's tale," without any scientific evidence, so far as I am aware, to support it, but it may serve to illustrate the point that to leave the source of contagion untouched, and to discard all safeguards except the mosquito netting, may be a perilous course.

The matter wears another aspect if the Culex fasciatus serves as a necessary intermediate host, essential to the full development and activity of the yellow fever germ, whatever that may be, so that if we could exterminate this particular mosquito, the disease would die out without other measures being taken. Then yellow fever would resemble in its origin, and ought, we think, to resemble in its course, malarial fever, filariasis, and other parasitic diseases imputed to the agency of the mosquito. Indeed, Dr. Reed lays stress upon this analogy supposed to be existing between malarial and yellow fevers. But malaria is confined to definite localities, where it always prevails; it never sweeps over a continent in frightful epidemics; it is generally chronic in its course, often causing permanent lesions in the system; one attack does not confer immunity. In short, for diseases having similar origin, there could hardly be greater divergence. The analogy with malarial fever, so far as the course of the disease is concerned, breaks down at every point.

Even as to the similarity in origin, we are by no means on sure ground. Yellow fever can easily be conveyed from the sick to the well by direct blood inoculation, so the Culex fasciatus is not an indispensable intermediary.

There is considerable doubt whether malarial fever can be conveyed in this way, notwithstanding certain recorded experiments that seem to prove that it can be. The latest English medical writer on this subject says: "It is doubtful, judging from our knowledge of the double cycle of the life of the sporozoa, whether man or animals can be infected with malaria by injections of malarial blood" (Christy, "Mosquitos and Malaria," 1900, p. 60). If the law enunciated by Grassi can be established, "no mosquito, no malaria," then the analogy breaks down absolutely. Anyway, a great deal is being assumed upon the strength of a doubtful analogy, for an organism no one has ever yet seen.

In these days of rapidly changing views, the work of no investigator, however eminent, should be held absolutely conclusive unless it has been verified by many others working on independent lines, and still less should changes be made in the quarantine laws. Fortunately, in this instance, little or no harm will result to the public, the changes being more apparent than real, for under cover of destroying mosquitos that may be lurking in the clothing and bedding of the sick, the same effective measures will be taken as heretofore to prevent the propagation of yellow fever by fomites.

EDWARD M. MERRINS, M.D.

NEWARK, N. J.

OUR LONDON LETTER.

(From our Special Correspondent.)

ABOUT CONGRESSES AND MEETINGS — THE MEDICO-PSYCHOLOGICAL ASSOCIATION—THE LUNACY REPORT—LONDON HOSPITAL NEW LABORATORIES—THE HUGHES-BENNETT LABORATORY AT EDINBURGH UNIVERSITY—RECENT DEATHS.

LONDON, August 9, 1901.

YET another Congress! And one more! The British Dental Association met on the 3d and sat for three days. There was a large attendance of members from all parts of the country, and numerous visitors from America and the Continent were present. The retiring President, Mr. George Brunton, in his valedictory address, referred to the loss sustained by the association in the death of Sir E. Saunders and the other supporters who had died during the year. The report referred to the difficulty of obtaining further legislation when the pressure on Parliament is so great, indirect advertising, and the absence of complaints as to the using of the title "dentist." The report went on to say that efforts on behalf of soldiers and sailors had induced the naval and military authorities to consider the dental necessities of our forces. Accordingly four dental surgeons have been sent to South Africa, selected, together with proper equipment, by the executive of the association. "Although this is but a small step, the report says, "we must look upon it with such satisfaction as one always does when the thin end of the wedge finds its way into an opposing mass."

The report was adopted, and it was decided to hold the next annual meeting in North Wales, Mr. Harding of Shrewsbury being appointed President-elect.

Mr. S. J. Hutchinson succeeded Mr. Brunton in the chair and delivered the presidential address. He offered a hearty welcome to visitors and went on to say that the Association of Dental Faculties in America was trying to do a meritorious work in levelling up the standard of education so that at least a minimum might be assured. State examination boards, he said, had been formed, insuring a standard examination all over America, which was the only qualification to practise, so that holding a diplome gave no authority to practise unless supplemented by passing a State examination. Such a plan he considered ought to work well, but he did not see a definite provision to enforce preliminary education and examination as required of English students. He felt sure that in any movement for reciprocity England would have the support of most gentlemen holding high positions in America, either educational or professional, in making the curriculum efficient in arts and sciences as well as in dental education. The education department and other branches of the public service were becoming alive to the importance of attention being paid to the teeth; but he regretted that the London School Board had not availed itself of the opportunities it had to provide for the children under its care. On the other hand, the War Minister had taken a step which he hoped would eventually lead to a dental department of the R. A. M. C. He then drew attention to the new dental hospital as the embodiment of all the newest improvements in hospital construction, and as containing every appliance for the treatment of suffering from the teeth, as well as a magnificent dental school fully equipped for successful teaching.

In the afternoon a reception was held in the new hospital by the Dean and professional staff. In the evening the President and Mrs. Hutchinson received the members and lady friends at the London University, South Kensington, this being the first occasion on which the University has lent its new quarters for a social entertainment.

The other Congress to which I alluded as one more (but there are yet others) is the pharmaceutical conference held this year at Dublin, Mr. Druce, M.A., being President. His inaugural address was delivered on the 30th ult., and I am assured was as remarkable for its rhetorical power as for its wealth of scientific information. It consisted very largely of a review of the progress during the past century of the sciences connected with pharmacy. Botany, as the President's particular occupation, claimed a high position in his review, but he showed great familiarity with the other branches of science involved. There was a reception at the Museum of Science and Art the evening before the address, and after it there was a luncheon at the Mansion House.

The sixtieth annual meeting of the Medico-Psychological Association may be regarded as a sort of congress too. It was held at Cork under the presidency of the resident physician of the asylum there, Dr. Oscar T. Woods. About sixty members representing the specialty from all parts of these islands attended the meeting, and a number of papers connected with the subject of insanity were read and discussed..

The fifty-fifth annual report of the Commissioners in Lunacy was issued as a blue book on Saturday. The total number of lunatics on January 1, 1901, was 107,944. That is an excess of 1,333 on the number on that date in 1900. In 1899 the increase was 1,525; in 1898 it amounted to 3,114. There is, therefore, considerable variation, but a generally increasing number of persons are brought under the notice of the Commissioners.

A considerable addition has been made to the London Hospital and School by a new building, which serves as a mortuary, post-mortem room, and pathological laboratory. The last is on the first floor and has a distinct entrance. There is quite a large laboratory, a bacteriological room, a chemical and a research laboratory with rooms for the director, his assistants, and others. The equipment seems complete, and the arrangements are all of the most recent description.

Mrs. Cox has made a worthy tribute to her father, the late Professor Hughes-Bennett, in presenting to the Edinburgh University, where he taught from 1848 to 1874, a laboratory for experimental physiology. Few memorials could be more appropriate. Hughes-Bennett, though so great a clinical teacher, was an experimental physiologist, and he made his science the basis of his teaching. By the bedside he was very practical, and men are living in all parts of the world who owe much to him. But their number, alas, is rapidly diminishing, for it is more than a quarter of a century since he died, though his works still follow him, and Edinburgh will now have a constant memorial of one of whom she is still proud.

Among recent deaths that of Carsten Holthouse is noteworthy, and seems to carry us back into the last generation; for he had nearly completed his ninety-first year, being born in October, 1810, and dying July 18, 1901. He enjoyed good health till about two years ago, but he had retired from practice several years before that time. He became consulting surgeon to the Westminster Hospital in 1875, having given the best years of his life to its service. The Medical School of that Hospital really owes its existence to him; for, though previous efforts had been made to establish it, they were quite unsuccessful until he took it in hand and brought it prosperity. His writings on hernia and on ophthalmic surgery were of considerable value. He was a sound surgeon and a well-informed man. It was a pleasure to meet him.

Dr. J. St. Thomas Clarke of Leicester, died suddenly on the 2d inst. Last year he was the victim of an attack by a lunatic, who fired four shots at him with a revolver and wounded him in the lower spinal region. After some weeks he recovered sufficiently to give evidence before the magistrates.

Two notable provincial physicians died on the 21st ult. One was Dr. R. C. Shettle of Reading, who was physician and subsequently consulting physician to the Royal Berkshire Hospital. He retired in 1897. He was sixty-seven years old. The second was Dr. E. S. Morley of Blackburn, J.P., who was born in 1828. His name is known as a great authority on athletic sports, in which from youth to age he was an enthusiast. He was a younger brother of the politician.

Another medical magistrate, Dr. J. S. Slater, J.P., Mayor of Evesham, died after only three days' illness on the 25th ult., aged fifty-four.

Book Reviews.

How to Cook for the Sick and Convalescent. By Helena V. Sachse. Philadelphia: J. B. Lippincott Company, 1901.

Fortunate the invalid whose friends consult this book. Convalescence is at best a dreary season, rendered doubly so from the monotony of the food prescribed by the physician and conscientiously prepared by nurses and caretakers. Who does not sympathize with the child who, after long weeks of tedious feeding, suddenly sat up in bed and exclaimed, "Not another mouthful of nourishment will I take. I want my dinner!" This could scarcely have occurred had Miss Sachse's book been taken as a guide. Even the "slops" of invalid diet are here made varied and palatable, and when the patient is in condition for viands of a higher plane, capricious indeed must be the appetite that could resist the witchery of the preparations of egg, of oysters, fish, chicken, sweetbread, mushrooms, and other delectable dishes mentioned. Such delicate feasting must have pleased even the fastidious Theodore Child, and ought to wheedle even a pessimistic and melancholic invalid into eating and living in hope of the next meal. A preliminary chapter so classifies the recipes that it is easy to turn to those containing no starch or sugar, or no starch but a little sugar, etc.; gives measurements and a list of the necessary cooking utensils. The author states that she has carefully tried all the recipes given, and that they have been successfully used in six hospitals. She gives brief but valuable instructions as to the preparation and serving of the food, ending with the sensible advice, "Garnish the dishes, but be sure they taste as good as they look."

Diseases of the Intestines. By Dr. I. Boas, Specialist for Gastro-intestinal Diseases in Berlin. Authorized Translation from the First German Edition, with Special Additions by Seymour Basch, M.D., New York City. With 47 illustrations. New York: D. Appleton & Company, 1901.

In this volume we find the most recent ideas concerning the diseases of the intestines commonly met in general practice and treated by a master hand. Many things such as intestinal parasites are wisely excluded from the text, while great stress is laid upon affections which are common in office practice, such as chronic constipation, intestinal ulcers, rectal troubles, and intestinal neuroses, about all of which too little has been written.

The author urges the examination of the feces as a much-neglected art, though so valuable in diagnosis. His plans of treatment are eminently conservative, and his pathology and physiology are given with ample comprehensiveness. We know of no book on the subject which will be of greater aid to the practitioner.

In the introduction, the anatomical and histological aspects of the subject, along with the physiological and physiologico-chemical, are carefully described.

In the first part, the methods of taking a history, examining a patient, his feces, urine, and stomach-contents are all practically and scientifically treated. Then he teaches us what, in his vast experience, has been found most efficient in treatment of the intestinal diseases—diet, hydrotherapy, massage, electricity, lavage, enteroclysis hygiene, and drugs all being thoroughly considered.

In the second part he describes the special diseases *in extenso*. Acute and chronic intestinal catarrhs, constipation, ulcers, neoplasms, stenoses, appendicitis, and neuroses, together with rectal diseases, sum up a most interesting and painstaking exposition of the subject.

The translator has added many points on appendicitis which are commonly taught in America, and which differ materially from the continental opinions. In Europe, he states, the disease is considered as a much less serious one and quite amenable to treatment other than surgical, and in his additions to the text he quotes many of the leading American surgeons who are, as a class, decidedly in favor of operative interference.

In thus combining the experiences of continental and American authorities the author and the translator together give us a very broad view of the subject, and make it better adapted for American readers.

A Textbook of Diseases of the Nose and Throat. By D. Braden Kyle, M.D. Second edition; illustrated. Philadelphia: W. B. Saunders & Co., 1900.

A student's textbook of diseases of the special organs should aim to point out the interdependence that exists between general systemic diseases and those of the special parts under consideration. Furthermore it is essential to such a work to clearly show the relation between diseases of one certain special organ and those of its neighbors. In this way the student will come to look upon the special organs not as entities, but as parts of a mechanism all whose workings must be investigated when any of its components are disordered. Viewed from such a standard of essentials, the present volume does not satisfy. It is simply a portrayal of the pathological conditions to be found in the nose, throat, and larynx, with considerations on their diagnosis and treatment. The picture presented of the individual nose, throat, and laryngeal lesions is accurate and clear, and strengthened by numerous excellent illustrations.

The Syphilis of Children in Everyday Practice. By George Carpenter, M.D., London. New York: Wm. Wood & Co., 1901.

This is a handy book that will prove of value to the general practitioner and those not engaged in the specialty of venereal diseases. The volume is pregnant with facts, gathered from extensive experience with infantile syphilis. The descriptions are terse and clear. The illustrations are numerous, but almost too schematic.

Cliniques Médicales Iconographiques. Par MM. P. Haushalter, G. Étienne, L. Spillmann, Agrégés de la Faculté de Médecine de Nancy, et Ch. Thiry, Ancien Interne des Hôpitaux de Nancy. Paris: C. Naud, 1901.

This is an atlas, as distinguished from a treatise, of medicine, and as such is, of course, somewhat limited in its scope, since not all maladies, especially the non-surgical, possess external characteristics sufficiently pronounced to be capable of iconographic representation. There are many such, however, as we are reminded by reading the table of contents of this and the succeeding numbers of the series, and if all are depicted as are these in the fasciculus before us the work will be almost indispensable to the student and for consultation to the medical practitioner. The work will contain sixty-two phototype plates with nearly 400 pictures of about 300 different patients, and will be published in eight parts. The first fasciculus contains seven plates depicting progressive muscular atrophy, both myopathic and myelopathic, in its various types, accompanied by a descriptive text. The pictures are well executed and will enable one to recognize without difficulty the different forms of paralysis described. The text accompanying each plate consists of a brief report of the cases pictured, with a short general description of the disease in question. The atlas when completed will doubtless be a most useful supplement to any general medical treatise, especially to treating of diseases of the nervous system or of the skin.

A Manual of Diseases of the Nose and Throat. By Cornelius Godfrey Coakley, A.M., M.D. Clinical Professor of Laryngology in the University and Bellevue Hospital Medical College; Member of the New York Academy of Medicine, etc. Second edition, revised and enlarged; illustrated with 103 engravings and four colored plates. New York and Philadelphia: Lea Brothers & Co., 1901.

The first edition of Dr. Coakley's Manual received favorable notice in these columns. The present edition brings the various topics up to date and a new chapter is added on the general subject of "Affections of the Upper Respiratory Tract in the Infectious Diseases." The author stated in the preface of the first edition that he "had selected among the multiplicity of medicinal and operative measures those which in his judgment were the best." This is in our opinion one of the very best features of the Manual, for works of this kind are often padded with details of methods of treatment which have been tried and abandoned and are matters only of historical interest. While such facts may have their proper place in elaborate treatises, they are not suitable in a work designed for general practitioners. Their very number is apt to be confusing, so that the matter of therapeutics of the various maladies is not clearly set forth. We congratulate Dr. Coakley that a second edition of his Manual has been called for in so short a time.

The Medical News Pocket Formula for 1900. By E. Guin Thornton, M.D., Demonstrator of Therapeutics, Pharmacy, and Materia Medica in the Jefferson Medical College, Philadelphia. Third revised and enlarged edition. Philadelphia and New York: Lea Brothers & Co., 1901.

This little pocket edition seems to come out with the regularity of a year book of treatment. By the addition of new drugs in many prescriptions the formulæ have been brought well up to date. It is questionable whether as much reliance can be placed on formulæ put together by one man exclusively to cover all forms of disease as upon those carefully selected from the works of specialists and recognized authorities in the various branches with the name of the originator given.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 22, 1901.

The Management of Delirium Tremens, with the Report of a Case.—V. A. Ellsworth believes that neither hypnotism nor alcohol should ever be resorted to, since the former depresses the heart's action, and the latter acts as a depressant and continues the toxic condition. Out of 500 cases the author has had only two deaths, and these patients were in a state of collapse when he first saw them. He attributes his success (1) to the perfect freedom he allows his patients, that is, in not hampering their movements in the least; (2) to his keeping the room thoroughly ventilated, giving freely of cold water and good nourishment at short intervals; and (3) last, but not least, to his allowing no alcohol whatever.

On the Effect of Alcohol.—H. G. Beyer considers that the most recent researches have proved that alcohol has no nutritive value, but that, on the contrary, it causes an abnormal destruction of the protoplasmic constituents of the body. From his experience with sailors in the tropics, he has never seen any reason for recommending that alcoholic drinks be served out in regular rations. He has reduced alcohol to the rank of a drug, and prescribes it only for its temporary stimulant effect in cases of extreme fatigue. An army of five battalions of infantry and 2,300 coolies was ordered to move to the north coast of Atjeh, the expedition lasting five months. Alcohol rations were stopped, money being given instead. The operations were done under a tropical sun in a country full of malaria; the expedition was a complete success, and press, officers, and soldiers recognized the fact that it was in part due to the moderation with which they had indulged in alcoholic beverages. The endurance which this small army had shown had never been equaled in the history of tropical warfare, and had, up to that time, been believed impossible by most of the highest military officers in the Dutch East Indian Army.

Treatment of Delirium Tremens.—J. Frank Perry says that he has failed to find a sovereign remedy, but has to vary drugs to suit the cases. The heart is sustained with strychnine and nitroglycerin, and possibly digitalis, strophanthus, sparteine, or cactus grand. When the delirium tremens sets in, the one purpose to be attained is to get the patient to sleep as soon as possible. Of the many popular remedies, chloral hydrate, alone or combined with the bromide of potassium, holds the first place. There is, however, a small number of persons for whom its use would be hazardous because of its depressing effect on the heart. The author uses small doses at intervals of from fifteen to thirty minutes. In some cases chloral is absolutely inert. Musk is efficacious, but very expensive. Apomorphine, hyoscine, and morphine are fairly serviceable. The first can easily be pushed too far, but when intelligently used often acts admirably. Hyoscine is capable of injury and morphine is uncertain. When the delirious patient is once asleep he must not be disturbed, although he may not rouse for twelve or fifteen hours. When he wakes he must be treated by alcoholic substitutes (ammonia, camphor, hyoscyamus, valerian, capsicum, ginger, etc.) and heart tonics, and nourishment must be pushed to the utmost. At the end of twenty-four hours he will be literally a new man.

The New York Medical Journal, August 24, 1901.

Sulphuric Ether in the Removal of Ceruminous Plugs.—E. L. Meierhof has tried the various solvents used to facilitate the removal of ceruminous plugs, but has found none so good as undiluted sulphuric ether, poured from a small bottle or a suitable pipette into the external auditory canal. The ether acts in a few seconds, partly dissolving the cerumen from its attachment to the canal, so that with the most gentle syringing the plug is promptly removed. No dizziness nor other ill effect has followed this use of ether. For those who might hesitate at first to employ pure ether in the ear, a mixture of equal parts of ether and alcohol might be used, with perhaps the same effect.

A Case of Actinomycosis Hominis.—Gustav Futterer reports a case, and gives points in the differential macroscopical diagnosis between actinomycotic and tuberculous peribronchitis. The actinomycotic peribronchitis appears in fresh infections on cross-sections of small bronchi, in the form of sharply defined sulphur yellow rings, with clear round outlines against the unchanged parenchyma of the lung. The lung substance is rarely affected, and then late. The youngest as well as the oldest peribronchitic areas have the same sulphur-like color, while in tuberculous peribronchitis the color is very variable and, until there is cascation, gray or reddish gray. The tuberculous peribronchitic areas project above the surrounding lung tissue; they have an uneven surface and irregular outlines; they tend to spread peripherally, instead of spreading centrally and closing the lumina, and an early infection of the surrounding lung tissues is the rule. The tuberculous infection usually affects the apices first, but actinomycosis prefers the lower portion of the lungs. The author describes the supposed course of the disease in the case reported.

A Case of Angiosarcoma of the Nose.—Stanley S. Cornell reports the case of a woman suffering from stenosis of the left nostril, which had been developing for two years. No discharge had appeared, except bleeding, as if a lump in the nostril were picked; there was neither pain in the nostril, nor reflected pain in the facial regions, and no involvement of the eye. Examination showed a bluish gray bulbous growth entirely filling the left nostril. It was intensely vascular, and a considerable flow of arterial blood followed the insertion of a probe to the extent of one-eighth of an inch. The growth was removed by operation, and examination proved it to be angiosarcoma, and extremely vascular. The cells were mainly spindles, mixed with round cells (of connective tissue) and leucocytes. The surface was covered with epithelium—in most places several layers in thickness. Beneath this layer the fibrous tissue organization was marked. The patient is doing well, breathes clearly through the nose, sleeps with closed mouth, uses no nasal douche, has no discharge from the operated nostril, and is subject to no pain in any region of the head.

Philadelphia Medical Journal, August 24, 1901.

Peliosis Rheumatica.—T. Avery Rogers reports in detail a case of this disease in a woman nineteen years old. The case tends to uphold the theory that the cause of the disease in some instances is a systemic infection from the presence of a pyogenic focus. Three months prior to the attack the patient had a mammary abscess, which was lanced, and from which she made an uneventful recovery; the wound opened and discharged slightly two or three weeks after the attack of peliosis, from this the author concluded that the suppurative condition was an etiological factor in the production of the peliosis.

The Intimate Action of the Silver Nitrate Injections in the Treatment of Phthisis.—Thomas J. Mays bases his treatment of phthisis by the hypodermic injection of silver nitrate over the vagi, on the hypothesis that pulmonary phthisis is largely primarily a neurosis in which the vagi participate, and that direct stimulation of these nerves favorably influences the pulmonary condition. He concludes that the mechanism of the silver nitrate injections is of such a nature that it arouses the vagi from a feeble to a more vigorous action, in this way creating an antagonism to the disease which diffuses itself throughout the ramifications of these nerves.

Medical News, August 24, 1901.

Carbolic Acid in Burns.—Otto L. Muench advocates the application of pure carbolic acid to burned surfaces, having used the same with most excellent results in cases of small burns of the first degree, in a case of scalding involving the chest, neck, and shoulders of a twelve year old child, and in a case in which the "entire head, face, neck, and hands were one burn." The application of the acid stops the pain by producing local anæsthesia of the peripheral nerves, and its escharotic action is neutralized by coagulation of the albuminous effusion, this latter completely excluding the air and preventing infection.

Further Notes upon the Diagnostic Test of Tuberculin.—Edward O. Otis reports sixty-two tests made to determine how many cases of known syphilis react to tuberculin and also the reliability of the test in suspected or incipient tuberculosis. In thirty-six cases of syphilis tested with tuberculin there were undoubted reactions in seventeen per cent.; in twenty-six cases of suspected or proved tuberculosis, there were reactions (including abortive ones) in thirty-one per cent.; in eight cases showing tubercle bacilli in the sputum there were reactions in fifty per cent.; of three cases showing tubercle bacilli, two did not react; seven, five, and ten milligrams were used respectively in two of these cases; two, five, and eight in the third, giving only a local reaction. The author offers no explanation for these unexpected results. In eighteen cases of suspected tuberculosis there were six reactions. He concludes that while confidence in the test is apt to be shaken by the failure to obtain reaction in a case of tuberculosis not far beyond the incipient stage with tubercle bacilli in the sputum, the possibility of error in such investigations must not

be lost sight of. No injurious result need be feared from doses up to ten milligrams.

Strangulated Hernia of the Bladder; Ruptured Sarcoma of the Testis Mistaken for Strangulated Hernia.—Thomas H. Manley, reviewing the literature of vesical hernia, concludes that the condition is not uncommon, three cases having come under his own observation. There do not appear to be any characteristic symptoms of vesical hernia and its presence as a complication does not seem to cause special discomfort. He reports in detail one case on which he operated successfully. In this case there were all the symptoms of strangulation. Operation revealed a vesical diverticulum slipping out through the crural ring, becoming distended and provoking inflammation at the point of constriction, the pent up urine producing excessive irritation with reflex pain over the entire abdomen. The author advocates operation in these cases without a transfer to hospital to avoid the violence of transportation. The chief features of his operative technique are: (1) A large incision involving laparotomy; (2) free division of the constriction from without inward; (3) deliberate, methodical, and complete treatment of any important complication at once. He reports a case of ruptured sarcoma of the testis which had been clinically diagnosed as strangulated hernia.

A Study of Burns, with a Plea for Their More Rational Treatment.—Frederic Griffith believes that burns should be treated in accordance with general surgical principles. Their pathology is that of local inflammation with the resultant complications, two degrees of severity being recognized; burns of the first degree involve the skin only, all others belong to the second degree. Early death and internal complications following burns are due to the direct action of heat; later effects follow from infection of the burned area. The amount of contraction and subsequent deformity is determined by the condition of the granulations during healing, irritation causing larger granulations and consequently greater contraction. The local treatment of burns should be directed to the prevention of irritation. The wound should be cleansed of the burned tissues as thoroughly as possible; hydrogen dioxide being used to wash away débris and render the parts aseptic, and rubber tissue in strips should be laid on the wound to prevent contact with the absorbent dressing. Splints, to secure relaxation and retention of the burned part, are of great importance. The internal treatment is stimulative until reaction takes place, when it becomes supportive. Opium fulfils the indications for pain, internal inflammations, and diarrhœa; the bowels and kidneys must be kept open, the former by enemas only, and attention must be paid to signs of internal complications.

American Medicine, August 24, 1901.

Peculiar Nervous and Urinary Manifestations Following Grippe in the Aged.—O. P. Kernodle concludes, from a study of tabulated cases, that aged persons suffer more violently from influenza than those in youth and vigor; the manifestations are more marked and profound in the aged, and never entirely disappear; nephritis and urinary disturbances are more pronounced and lasting, and there is a more decided tendency to recurrence, resulting in death; owing to the worn out and deteriorated physical condition and lowered nerve resistance, the results are more grave, the assaults more violent and profound, and the death rate much higher in persons over fifty years.

Indications For and Against Total Removal of the Human Stomach.—George Childs-Macdonald considers that the advisability of total removal of the stomach depends upon the diagnosis, age of the patient, state of the blood, the heart, preexisting conditions, metastasis, and proper preparation of the patient. The operation is performed for carcinoma of the stomach. Unless in patients of extreme vitality he would make the age limit fifty-five in men, sixty in women. A high percentage of white blood cells would be unfavorable for surgical interference; while a fair proportion of red cells and hæmoglobin would indicate the opposite. Absolute integrity of the heart must be present for a favorable prognosis. The prognosis is more favorable, other things being equal, in persons leading an active life than in others. Non-abstainers, beer drinkers, tobacco and drug habitués are unfavorable subjects. Any evidences of debilitating or exhausting process other than primary cancer and excessive emaciation should be contra-indications. As to the condition of the stomach, the most favorable indications for operation are a moderately dilated viscus with a freely movable tumor to the right of the median line. The preparation of the patient should include absolute mental and physical rest in bed for six or more days. The proper functioning of the bowels, liver, and kidneys must be attended to, food should be administered by mouth and rectum to the extent of the patient's assimilative power, and the function of the skin must be promoted by warm baths daily. The stomach should be well washed, and a rectal injection given on the morning of the operation.

Journal of the American Medical Ass'n, August 27, 1901.

Cæsarian Section as a Method of Treatment for Placenta Prævia.—William J. Gillette says that the cases operated upon are as yet so few in number that no accurate deductions can be drawn from them, but he thinks it must be granted that cæsarian section, if generally adopted for placenta prævia, will reduce the fearful fœtal mortality, which we now have, to at most ten per cent., and when ninety-three consecutive cæsarian sections in the hands of three men (Reynolds, Leopold, and Evarts) can be done without the loss of mother or child, we have reason for our faith that it can be done without increased danger to the mother over what she must incur by any of the older methods. When the uterus does not contract firmly, thus rendering further hemorrhage and sepsis probable, or when the patient is unable to stand additional shock, the Porro-cæsarian section is the only procedure warranted.

Leucocyte Counts in Hemorrhage.—George Douglas Head reaches the following conclusions: 1. In dogs a diminution in the number of white blood cells in the circulating blood immediately follows a profound hemorrhage. 2. This inital leucopenia is followed sooner or later by an increase in the number of leucocytes in the circulating blood. This is the so-called post-hemorrhagic leucocytosis of all writers. 3. This leucocytosis of hemorrhage continues for at least seven days, and in some cases much longer. The writer believes that what he has demonstrated in dogs is equally true for human beings, viz., that immediately following hemorrhage there is a decrease in the number of leucocytes in the circulating blood. He says that this has been heretofore overlooked because hematologists have failed to make their counts soon enough after the bleeding took place.

Uric-Acid Inflammation of the Middle Ear, Membrana Tympani, and Mastoid.—Cornelius Williams believes that nine-tenths of all the inflammations of the middle ear and mastoid as observed in the Northwest, are due to uric-acid poisoning. They occur in summer and winter, but most frequently in late winter and early spring, and in persons of all ages. Those affected, according to his observation, are always persons who eat nitrogenous food in excess of their requirements. The adults are meat eaters almost to the exclusion of vegetables, and the babies are bottle fed. There is usually a distinct history of gout or rheumatism or of intestinal disorder due to fermentation or putrefaction. Ice and local measures can be freely used, but cases do better with than without the salicylates. Powdered opium is best for the relief of pain, but if the mastoid should become involved, it should be opened at once.

Tuberculosis of Animals in Some of Its Relations to Human Tuberculosis.—D. E. Salmon reports several cases which he considers prove conclusively that bovine tuberculosis is communicable to man. The question has been asked, if bovine tuberculosis is dangerous to man and is increasing, how is it that phthisis is decreasing? The conditions of life and of sanitation may be so improved as to counteract the increasing danger of infection, but apart from this, tuberculosis of the lungs is usually contracted by inhaling the infection, while if the disease is communicated through the food, it would probably take some other form, as tabes mesenterica, tuberculous, meningitis, etc. It is plain, from statistics, that in some countries where bovine tuberculosis is very frequent, there is also great frequency of tuberculosis in children. Admitting the subordinate rôle played by digestive infection in human tuberculosis, and that in England there is but one such case to nine cases of all forms of tuberculosis, still the matter is one deserving the most careful consideration of the sanitarian.

The Antenatal Treatment of Hæmophilia.—J. N. Ballantyne reports a case in which a woman with a distinct hereditary history of hæmophilia, shown in the form of postpartum hemorrhage and profuse menstruation and in the procreation of hæmophilic male infants, was treated during pregnancy with ten grains of chloride of calcium daily, with arseniate of iron and strychnine, from the sixth month to labor. She passed through confinement without hæmorrhage and was delivered of a male infant without hemophilia. This may have been a mere coincidence, but there is a chance that it was the result of treatment. It may be taken for granted that the chloride of

calcium reached the fœtal tissues, as undoubtedly the other medicines did also; in the second place, there is evidence that chloride of calcium is beneficial in hæmophilia after birth; and in the third place there is the extraordinary power of recovery possessed by the fœtus. If the *vis medicatrix naturæ* be greatly exaggerated in the fœtus, is it not possible that even the hereditary maladies may, if properly influenced, show a tendency to cure during ante-natal life? May it not be that medicines acting upon the organs and tissues, while these are still in the stage of construction, are more efficacious than when they act upon structures which are, as it were, set aside for health or disease?

The Lancet, August 17, 1901.

Atypical Empyema in General Practice, with Illustrative Cases and Critical Notes.—C. C. Baxter Tyrie reports a number of cases illustrating the varying behavior of pleural effusions. He explains the sudden deaths that occur as follows: Untoward disturbance of a patient results in a generalization through the pleural sac of a previously localized pressure. As a result of the attendant pulmonary collapse a previously impaired respiratory capacity of four-fifths or three-sixths is suddenly reduced to one-fifth in an already debilitated subject. Further, an appreciation of the great sensitiveness of the cardio-inhibitory center in the medulla, and the countless afferent paths from the thorax available for transmission of unauthorized stimuli, establishes the absurdity of advancing such anatomical and physiological absurdities as "twisting of the vessels," and so on.

Experiments with the Danysz Rat Bacillus.—E. Klein and Herbert Williams give the results of experiments undertaken with the view of ascertaining whether the culture of the rat bacillus is capable of causing death to a large percentage of rats fed on it. In the laboratory, the feeding experiments with cultures produced death in only thirty-three per cent. in between eight and fourteen days. Of rats fed on mice which had died within forty-eight hours after being subcutaneously injected with virulent culture, none died. Of six rats fed with similar material from guineapigs, four died from the disease in eleven, twelve, fifteen, and eighteen days respectively. Experiments in feeding on a large scale were carried on in a dock warehouse, but the results were wholly negative, and therefore the expectation of the medical health officers of a wholesale destruction of rats by Danysz rat bacillus as a preventive measure against plague cannot be considered as likely to be realized.

The Comparative Virulence of the Tubercle Bacillus from Human and Bovine Sources.—Mazyck P. Ravenel concludes from the results of experimentation: 1. That the tubercle bacillus from bovine sources has in culture fairly constant and persistent peculiarities of growth and morphology by which it may tentatively be differentiated from that ordinarily found in man. 2. That cultures from the two sources differ markedly in pathogenic power, the bovine bacillus being the more active for all species of animals tested, possibly excepting swine. 3. That tuberculous materials from cattle and from man correspond closely in comparative pathogenic power, in all test animals, to pure cultures of the tubercle bacillus from the respective sources. 4. That it is a fair assumption from the evidence at hand, and in the absence of evidence to the contrary, that the bovine tubercle bacillus has a high degree of pathogenic power for man also, this being especially manifest in the early years of life.

A Case of So-called "Fœtal" (or Congenital) Rickets.—Henry Ashby describes the case of a child which, at the age of fourteen days, had sustained fractures of the right humerus and radius, and of the left humerus, ulna, and femur, although there was no history of anything like violence. There was marked craniotabes, and the ribs also were abnormally soft. The child was well nourished and apparently born at term. The fractures mended well, but at six weeks the right femur fractured. At nine months the infant had cut two teeth, was bright and intelligent, without any signs of rickets or deformity of the bones. The author connects the condition of the infant's bones with the fact that the mother was forty-six years of age, had become more or less debilitated with child-bearing, and had suffered from illness during the greater part of the pregnancy. The case suggests rickets, but a certain amount of caution is required in asserting that it was true rickets, in the absence of a post-mortem examination and of a careful examination of the bones by modern methods.

British Medical Journal, August 17, 1901.

Neutral Red in the Routine Bacteriological Examination of Water.—William G. Savage, from an examination of fifty waters, using neutral red for detection of the colon bacillus, concludes that a positive reaction, while not absolutely diagnostic, points strongly to the presence of this organism, and a negative reaction renders its presence highly improbable. The test is of great value in the routine examination of water; it is easily applied, and with reasonable care errors can be avoided.

The Fallacy of the Permanganate Disinfection of Wells (Hankin's Method).—M. L. Dhingra considers that Hankin's method is fallacious in theory, defective in technique, and impossible in application. It is based on the assumption of a distinct relationship between the chemical composition of water and the number of microbes, which probably does not exist in nature. Further, there is not a single reliable experiment in support of this method; it has failed in practice after a prolonged trial. Permanganate neither diminishes the number of vibrios nor shortens cholera outbreaks.

Chronic Brass Poisoning.—William Murray recognizes a chronic poisoning in persons who work in raw brass quite distinct from the acute brassfounder's ague, and urges the adoption of preventive measures by legislation. The disease, when first seen, closely resembles consumption; later, the symptoms of chronic copper poisoning are present. Authorities do not agree as to the ultimate cause of the disease, some attributing the symptoms to the copper, others to the zinc, present. The poison, whichever it may be, enters the body in the form of fine dust by the respiratory and digestive tracts. The writer has successfully employed pure phosphorus or phosphoric acid in the treatment of this condition.

Port Sanitary Administration and the Control of Plague in the Port of Bombay.—P. Targett Adams gives a detailed account of the method of procedure relative to the departure of vessels from a plague-infected port. Briefly, three medical examinations are made of crew and passengers; those permitted to embark are stamped (on the forearm with aniline ink) with the date and place of examination; no article is allowed to be taken on board until it is disinfected and stamped; every person going on the ship must show a stamped permit from the port health officer, and when the ship is ready to sail, there is a final examination, and all stamped permits, luggage, etc., are examined and compared with the lists kept at the disinfecting station. The sanitary condition of the ship is inspected. While the author believes that the plague is in many instances conveyed by rats, he thinks there are many other modes of transmission, some even yet unknown, and urges that every avenue be guarded.

Münchener medicinische Wochenschrift, August 6, 1901.

Two Cases of Carbolic Acid Gangrene.—Fischer describes two cases in which the application of a weak carbolic acid solution to slight injuries produced local gangrene, and, as the patients were brothers, he assumes a family idiosyncrasy for the drug. Both men were young and had never suffered from any previous illness, and the application of a moderate amount of a solution, subsequently determined by litration to contain only 1.7 per cent. of the acid, caused gangrene of the fingers, making amputation necessary.

The Treatment of Motor Aphasia after Cerebral Disturbances.—Vidal recommends a system for training the articulating power of aphasics, the essentials of which consist in an analysis of the patient's speech, or attempts at speech, and systematic drilling on the sounds or their elements that are defective by means of direct study and imitation of the movements of the teacher's organs of speech, and practice before a mirror. Ordinary motor aphasias yield quite readily to this form of treatment, but when, in addition, there is amnesia the difficulties are much greater, since the loss of memory makes progress very slow.

The Treatment of Sarcoma with the Röntgen Rays.—Carl Beck reports very favorable results in a case of melanosarcoma treated by means of the *x*-ray. The growth developed on the outer side of the left ankle of a man of thirty-six, apparently originating in a birth-mark. Extirpation of the growth, as well as removal of secondary glands in the groin, was followed by relapse on two occasions, amputation being refused by the patient. After the second operation sarcomatous nodules appeared on the inner aspect of the calf, and as amputation at this late stage did not promise much, after a third excision the sarcomatous focus was exposed to the *x*-rays, first for ten, then twenty, thirty and forty-five minutes at a time, at intervals of two to three days. At the time of writing, nine weeks after the operation, there was no recurrence, and while it is too early to draw positive conclusions, it seems likely that, particularly in instances such as some breast cases, where the whole of the neoplasm

is not accessible to the knife, this method may with advantage be used to supplement the surgeon's efforts.

A Crystalline Immunization Product.—H. Buchner and L. Geret supplement their former observations on this body by reporting on the results of investigations undertaken to determine more accurately its nature. It appears that the first stated belief that its presence indicates a specific reaction is unfounded, and that the so-called "globulites" are purely inorganic, consisting of borium sulphate. The borium is contributed by the pepton solution, which contains enough of the element to produce the reaction, though the amount is so small that it escapes all but the most delicate tests. The formation of globulites, therefore, indicates merely that the serum tested has already been subjected to preliminary treatment by the injection of pepton or of blood. Further observations on the local reaction, produced by introducing pepton solution in sterile tubes beneath the skin of animals, the result being the precipitation of globulites, presumably through the intervention of the leucocytes in setting free sulphur, leads the authors to the conclusion that these cells are the producers of the ordinary immune bodies.

Deutsche medicinische Wochenschrift, August 8, 1901.

The Differential Diagnosis Between Appendicitis and Typhoid.—R. Mühsam comments on the difficulty which is occasionally experienced in distinguishing those two diseases, and describes a case in which operation for supposed appendicular disease revealed a healthy organ. The patient was a middle-aged man, who was suddenly taken with chills and severe abdominal pain. At the time of coming under observation there were localized pain and tenderness at McBurney's point, moderate temperature, and slow pulse. There was no rigidity of the recti and no dulness. Under expectant therapy the pain increased greatly, and restlessness developed with rise of pulse and temperature. There was neither enlarged spleen or roseola, and it was assumed that typhoid fever could be excluded; but on operation and inspection of the appendicular region, the only evidence of disease was found to be a small blood-stained area on the surface of the colon, at which point the intestinal wall seemed greatly thinned. The mesentery and mesocolon contained large numbers of bluish, swollen lymphatic glands. The ulcer was invaginated and sewed over; further search for similar areas was unavailing, and the wound was closed in the usual way. The patient did not suffer in any way from the results of the operation, and after the disease had run the usual course of typhoid fever of moderate severity, he recovered. Inasmuch as the Widal and diazo reactions did not develop till several days later, it is difficult to see how the diagnosis could have been established, though a blood count, which might have been of use, was apparently not made.

The Effect of Alcohol on Uric Acid Excretion.—R. Roseman mentions various other investigations of this question, which have had rather inconclusive results. A research of his own was carried out on a healthy adult unaccustomed to the drug. The experiment extended over a period of thirty days, first ten days under normal conditions, then ten days, during which large amounts of water were drunk, with the idea of discounting any objection that a possible subsequent increased elimination of uric acid might be due to diuresis produced by the alcohol, and finally ten days, during which 75 c.c. of alcohol were taken daily in 1,500 c.c. of water. This dose at first produced distinct symptoms of intoxication, but tolerance was soon established. The results showed that the average daily amount of uric acid excreted during the normal and water periods did not differ appreciably from that eliminated on the alcohol diet. In the course of another experiment, conducted on a fasting individual, there was observed a total absence of uric acid from the urine for a period of two hours, a hitherto unrecorded observation on human urine. This was perhaps, however, due only to idiosyncrasy, but a distinct increase in the amount excreted was not obtained in either set of observations, and it seems that alcohol does not very greatly affect the amount of uric acid disposed of. Although this conclusion is at variance with the prevalent belief that gouty subjects, on an alcoholic diet, suffer an increase in the amount of uric acid given off, the author believes the problem is too complicated to be solved by a single set of analyses, and that clinical experience is the more reliable guide.

French Journals.

Typhoid Pleurisies.—According to A. Kichel, the bacillus of Eberth can exist in the lungs of typhoid patients, and by means of the lymphatics of these organs it can be carried to the pleura. From one standpoint, this pleurisy is not a typhoid pleurisy, but it is pleurisy in a typhoid patient. These pleurisies are almost always accompanied by effusion. The duration is variable. In some cases the affection terminates at the end of a fortnight; in others it lasts six weeks. Generally, it has a rapid development and tends to a natural cure. It rarely passes to the chronic stage or to suppuration. The clinical forms are multiple. As to the nature of the liquid, it may be serous, hemorrhagic, or purulent; its tendency is to become hemorrhagic. The diagnosis almost always calls for great care. The prognosis of the general disease is not sensibly altered by the development of pleurisy. The treatment is not special, varying according to the nature of the case; thoracentesis or pleurotomy may be demanded.—*Gazette des Hôpitaux*, July 30, 1901.

Contribution to the Medico-Legal Study of Imbecile Prostitutes and Vagabonds.—Paul Garnier and Wahl conclude that imbecility is a frequent cause of vagabondage and of prostitution. These unfortunates should be isolated from the general public both for their own sake and for that of society at large.—*Gazette des Hôpitaux*, July 30, 1901.

Some Points of Hygiene and of Pathology in Hot Countries.—Vincent calls attention to the three kinds of rays which emanate from the sun, viz., chemical, light, and heat. He points out the different effects of these rays. Prisoners brought from their dark dungeons and exposed to the bright sunlight, reflected from a white wall, not infrequently become blind. Sunstroke is caused by the direct action of the sun's rays, while heat stroke is caused by an overheated atmosphere. The treatment of both these affections consists in the application of ice to the head, cold applications to the body, fresh air, and rythmical tractions of the tongue. The writer then speaks of the food value of sugar. It has been reported that among soldiers who, in very hot countries, were allowed to have as much sugar as they desired heatstroke was extremely rare. Sugar has not, as a stimulant, the inconvenience of alcohol. It builds rapidly up muscular energy, without having a later depressing action. Sugar is easy to carry, and can be kept in good condition with a little care.—*La Tribune Médicale*, July 17, 1901.

Acute Delirium Considered Clinically, Pathologically, and Bacteriologically.—Roubinovitch characterizes acute delirium by its extreme gravity and rapid development. This affection is observed in the course of, or following mental troubles. Sometimes it is primary. Among the determining causes are alcoholic excess and violent emotions. Among the prodromal symptoms are cephalalgia, general malaise, loss of appetite, constipation, nightmare, insomnia, and extreme irritability. These symptoms last for some days. There are two phases of the disease, the one of excitement, the other of collapse. As to its pathology, there have been noted hyperæmia of the meninges, œdema and active congestion of the brain, and venous cerebral congestion. There have been reported congestion of the intestinal mucosa, as well as ulceration, diffuse fatty degeneration and pigmentary atrophy of the hepatic cells, hemorrhages into the renal glomerule, and muscular degeneration in various parts of the body. The microorganisms found in these cases have been varied. Bacteriological researches tend to demonstrate the toxi-infectious nature of acute delirium.—*Le Bulletin Médical*, August 3, 1901.

Treatment of Typhoid Fever by Cold Injections.—Lemoine states that although the present treatment of typhoid fever consists in the administration of cold baths, nevertheless there are cases in which, from one reason or another, it is impossible to pursue this routine. In such cases which have come under his care he has substituted injections of cold water which are perhaps more of the nature of a douche or irrigation than an injection. The injection, like the bath, is given every three hours—or, indeed, every two hours if the temperature rises rapidly to a high degree. The water used is of a temperature of 18° to 20° C. (64.5° to 68° F.). The quantity used each time is two litres, and is allowed to flow into the bowel gently under light pressure. The water is boiled before using. The effects are two-fold, viz., lowering of the temperature and disinfection of the intestine. The nervous symptoms are much relieved, and the patient preserves a good appetite. The rectal sound is introduced to a distance of twenty cm. Every injection is followed by an evacuation of fecal matter, and the stools are rare in the intervals. It is to the disinfection that the writer attributes the fact that, in general, patients treated in this way have a lower temperature than those treated by baths. He believes this method has not been sufficiently tried to give valuable statistics as yet. In thirty-two cases he has had only one death, a mortality of three per cent. —*Le Nord Médical*, August 1, 1901.

BRITISH MEDICAL ASSOCIATION.

Sixty-ninth Annual Meeting. Held at Chelten[ham] July 30, 31, August 1, 2, 1901.

(Continued from page 310.)

SECTION OF TROPICAL DISEASES

First Day—Wednesday, July 31.

THE proceedings of the section were opened [by] JAMES CANTLIE, the Vice-President, who explain[ed] that the President was now in Africa, conducting experiments looking toward the extermination of mosquitos in [the] regions where pernicious malarial fever barred the [ad]vance of civilization. He then read the

President's Address.—Major RONALD ROSS had [chos]en as the subject of his address a review of the advances made during the past year in our knowledge of tropical diseases.

Yellow Fever.—To America, he said, belongs the [hon]or of discovering one mode of infection at least, physicians in that country having for some time past sought an experimental verification of the theory of Finlay and others in regard to the propagation of yellow fever by mosquitos. The experiments had been conducted with scientific accuracy, and no doubt remained as to the soundness of the conclusions reached, in spite of the absence of a parasitological basis for the theory. Great heroism had been shown by those subjecting themselves to tests. In addition to the death of Dr. Jesse W. Lazear in Cuba, there was to deplore that of Dr. Walter Myers, who had died from yellow fever while studying it in Brazil. Should the pathogenic organism of yellow fever prove to be a vegetable organism, it would suggest the not improbable view that suctorial insects may transfer vegetable as well as animal parasites. Some epidemiological facts suggest infection by gnats in Malta fever and perhaps leprosy, and by other vermin in relapsing fever, typhus, and some skin diseases.

Ankylostoma Duodenale.—Annett's confirmation of Giles' life-history of these dangerous and widespread parasites throw a vivid light on the route of infection adopted by them.

Malta Fever.—Wright has shown by his observations on the serum reaction in Malta fever, that it exists in India, Hong-Kong, the United States, the West Indies, and Brazil.

Malaria.—Numerous observers have maintained the advance in our knowledge of malaria. In the British possessions, several have made isolated efforts to deal with malaria, but the country generally has done little. British workers, however, have closely studied details of the malaria question in various parts of the world. Many experimenters have succeeded in direct cultivations of the parasites—in anopheles. Manson has reported the infection of healthy persons in London by mosquitos brought from Italy, and the preservation in health of others in a mosquito-proof house in the Campagna. Nuttall and Shipley, Christophers and Dutton, have closely examined the anatomy of mosquitos. Nuttall, Cobbett, and Strangeways-Pigg have made interesting researches on anopheles in England. Until we know, however, why individual anopheles so often resist infection, as they do in England, negative experiments with culex cannot be entirely convincing.

Beriberi.—Owing to the similarity in symptoms, Major Ross suggested, it is possible that cases supposed to be beriberi are really due to arsenic poisoning.

In speaking of the work of the future, he said that researches are urgently required in connection with (1) tropical fevers; (2) the flora and fauna of the intestine in tropical bowel complaints; (3) the question whether European children in the tropics suffer as frequently from malaria as the children of natives. Measures should be taken looking to the extermination of mosquitos in tropical cities.

Stone in the Tropics.—Mr. P. J. FREYER of London opened the discussion on this subject, confining his remarks to an account of his personal observations in India. The geographical distribution of stone in India would throw light on the cause of urinary calculi. He was not dealing, he said, with the phosphatic variety, which probably has its source in disorders of the urinary tract, but with the oxalate of lime and uric acid calculi which originate differently.

Surgeons in India did not often see cases of prostatic enlargement, because the natives ignored surgical assistance. The prevalence of urinary calculi among the inhabitant of the plains bordering on the Indus and the Ganges, might doubtless be traced to the use of the lime-impregnated water of these rivers. It was supposed that, in the great heat of summer in the infected districts, crystalline deposits resulted from extreme concentration of the urine, while the comparatively severe winters induced impaired liver action. Dietetic errors could not be invoked as a cause of stone in India. Wheat, barley, and other cereals were much eaten in the districts where stone exists, which exonerated rice from the charge of causing it. Mohammedans eat flesh in both Eastern and Western Bengal, but stone prevails in the latter area and not in the former.

Litholapaxy is the operation to be used par excellence. Lateral lithotomy gave a mortality of thirty per cent. in 1882. The statistics published in 1895 are the following: Out of 147 suprapubic lithotomies, 42.17 per cent. deaths; 7,000 perineal lithotomies, 11.45 per cent. deaths; 10,079 litholapaxies, 3.96 per cent. deaths. It is a mistake and unfair to assert that the greater simplicity of life of the native Indian than that of the European causes more recoveries after operation. The natives of India suffer from kidney disease quite as much as do Europeans at home.

Surgeon-General HARVEY, Director-General Army Medical Service, India, testified that litholapaxy had in India replaced lithotrity at several sittings. The poorer natives were alarmed by operation, and two patients had been known to disappear, after one or two sittings, still carrying fragments of stone. Three out of twenty-two cases operated upon by him by lithotrity had died. The whole world was indebted to Mr. Freyer and Colonel Keegan for their demonstrations of the value of litholapaxy.

Dr. PATRICK MANSON endorsed Mr. Freyer's opinion as to the removal of stone, but did not agree on the subject of etiology. The drinking of lime water he did not believe a causative of uric acid or oxalate of lime calculi. Stone is rare in some calcareous areas in Great Britain, and very common in certain granitic districts, as Aberdeenshire. Stone is prevalent in granitic Canton. It is known that a nucleus causes calculi in the forms due to foreign bodies and to the ova of Bilharzia, and a study of the nucleus may explain the geographical distribution. A parasitic cause is suggested by several facts.

Lieutenant-Colonel GILES thought the waters of the Indus and the Ganges were not limy, as the Himalayas are chiefly composed of gneiss and schist, but probably very like to the drinking waters in other parts of India.

Dr. SIMON of Singapore had met but few cases of urinary calculi during twenty-five years in the Malay Peninsula and in the Straits settlement, and these were imported.

Captain MILNE had found stone in India in non-calcareous districts, and thought it rare in some limy areas.

Dr. LEONARD HILL said that in Pakhoi, China, stone was absent, but was very prevalent in Canton, two hundred miles away. In Ning-Po it was almost unknown while common close by in Hang Chau.

Dr. MOFFAT had seen only one case in Uganda, and

that was a phosphatic calculus formed around a foreign body. The district had no limestone.

Mr. JAMES CANTLIE of London said that the great condition of success in litholopaxy was a perfect instrument, especially in the tropics, where caoutchouc rapidly spoiled. New instruments were hard to get, and this formed an objection to litholapaxy in remote parts of the globe. In large towns the operation was most desirable.

Professor T. M. SANDWITH of Cairo considered that a nucleus was the chief cause of calculus, and in Egypt this was the ova of Bilharzia in the majority of cases. Nile waters is full of lime, and is taken unfiltered by the Egyptian peasants, which may possibly account for the frequency of vesical calculus.

Mr. Freyer, replying, endorsed Mr. Cantlie's remarks as to the necessity of obtaining good instruments. Rubber, he thought, was preserved by frequent use, and would last as long in the tropics as elsewhere if used as often.

Dust as the Vehicle for the Germ of Cerebrospinal Fever.—Major W. J. BUCHANAN said that in a previous paper he had reported forty-seven cases of this disease occurring among prisoners in the Bhagulpur jail, and now adds thirteen more to the list. Fifty-seven of these cases were among prisoners working at "dusty" occupations, such as brick, field, and road work on the one hand, or wheat grinding, rice husking, etc., on the other. Only four of the cases occurred during the wet season, and these were grain-cleaners, the dust from whose work is not affected by the rain. Skilled laborers in spinning and weaving did not have the disease. Direct infection could be eliminated. Prisoners working in a shed at rice husking were provided with respirators, and the shed was thoroughly disinfected. No case has come from the shed in seven months, whereas eight cases came from it last year. The conclusion reached by Major Buchanan was that the germ of cerebrospinal fever, a diplococcus, is frequently disseminated by means of dust. This fever may justly be included among the continued fevers of the tropics.

Lieutenant-Colonel GILES referred to the recurrence of cerebrospinal fever in an Indian jail after thorough cleansing and disinfection.

Four Cases of Liver Abscess Treated by Trocar and Cannula and Syphon Drainage (Manson's Method).—Mr. JAMES CANTLIE had treated twenty-eight cases by Manson's method, with twenty-four recoveries. Four of these cases were described. Of the four fatal cases two were the first he treated, one was operated on, but not treated afterward, and the fourth was comatose and operated on only for the relief of symptoms. The four cases were intrahepatic abscesses, and all had suffered from dysentery. The best operation for these deep-seated liver abscesses is tapping by the trocar, and the introduction of a large tube and syphon drainage. A superficial abscess may be opened by any operation, but the cutting or free method is not to be advised in the case of deep abscess in the upper part of the liver, pressing upward toward the chest. Transthoracic operation is uncalled for, and both that and laparotomy are unjustifiable in the tropics, where, except in the large centers, the surgeon often has to work without assistants.

Mr. P. J. FREYER preferred incision to trocar and cannula, which he has quite abandoned.

Dr. G. P. JORDAN of Hong-Kong operated by incision, having given up the trocar and cannula. Rubber drainage tubes have a tendency to be compressed by the ribs, so he substituted silver.

Dr. CHISHOLM of Sidney operated by incision, because in Australia pus in the liver is usually secondary to hydatids, but he welcomed a simple method of operating for simple abscess.

Dr. MANSON advocated the useof trocar and cannula, and thought that British surgeons were somewhat too fond of heroic operations.

Capt. W. R. BALTYE said that severe hemorrhages had been known to follow puncture of the liver by the aspirator-needle, and thought that with an open wound such bleeding could be more easily checked.

Second Day—Thursday, August 1.

Notes on Anti-Malarial Measures now being taken in Lagos.—Sir WM. MACGREGOR, in opening the discussion on malaria, said that the colony at Lagos spends one-seventh of its revenue in combating malaria and dysentery. Every means was being taken to educate the people in regard to malarial infection, and to its prevention by means of gauze netting, the destruction of the breeding places of mosquitos, and the use of quinine. The majority of Government officers take quinine, two and one-half to five grains daily, as a prophylactic; no man should be sent to a malarial country who will not take quinine. It is a question how to protect the native, since one cannot give quinine to the whole population. Muslin cuts off too much air, mosquito netting mildews and rots, but a metallic gauze of galvanized wire netting is good and not dear. To diminish the number of mosquitos is fraught with difficulties. In inland towns the long dry season destroys the larvæ, and malaria is infrequent. It is not practicable to separate Europeans entirely from the natives.

The Prevention of Malaria in Hong-Kong.—Dr. J. M. YOUNG confirmed the fact of the etiological relation between anopheles and malaria in and about Hong-Kong. There were two varieties of anopheles, the *A. costalis* and *A. sinensis*. Clearing long grass and undergrowth, draining, etc., were efficacious remedies, as no mosquito will fly farther than one hundred and fifty yards. Dragon-flies, tadpoles, and small fish are supposed to be the enemies of mosquitos, and experiments have been tried with them in Hong-Kong. Culex larvæ destroyed the anopheles larvæ when placed together in the same pool.

Inoculation of Malaria by Anopheles.—Captain C. F. FEARNSIDE reported experiments in one of the most malarial jails in India, the Central Prison of Rajahmandri, Madras Presidency. About seventy per cent. of the mosquitos fed on malarial persons became infected, and seven out of the eight persons bitten by these mosquitos had the fever. Parasites of the estivo-autumnal and tertian varieties had an inoculation period of from twelve to twenty-five days. Native Indians, he said, will not use mosquito-proof houses or netting, and segregation, the general use of quinine, and the destruction of the anopheles present the greatest difficulties.

Notes on Cyprus Fever.—Dr. GEORGE A. WILLIAMSON said that Cyprus fever and Malta fever are often confounded, but the chief fevers in Cyprus are malarial of the tertian and quartian types and their doubles. Drainage, and other sanitary measures have greatly diminished the prevalence of the pernicious type.

Malarial and Filarial Diseases in Barbados, W. I.—Dr. GEORGE C. LOW had found no anopheles and no malaria in Barbados, but culex and filarial diseases were common. The water supply in the houses was good, and could the pools and tanks about houses be done away with, it was likely that filariasis would disappear.

Dr. EDWARD HENDERSON reported the tertian as the type of malarial fever existing in Shanghai. It was hopeless to expect that preventive measures against malaria would be adopted throughout China; still Europeans should set a good example to the Chinese.

Dr. MANSON thought that different measures of prevention applied to different places, and that no one measure should be exclusively adopted. Quinine could be given generally in small communities, but not in large ones; the natives could not be made to take it. Dr. Young

reported the destruction of anopheles larvæ by culex larvæ, but this occurred only when food was scarce. If we could ascertain why anopheles lived in certain places and not in others, and why certain diseases prevailed in certain localities, we could fight the mosquito with natural instead of chemical and mechanical methods, just as vine diseases are being treated in France and orange diseases in the United States. No one plan is perfect, but nothing should be decried which diminished the disease, even if it did not eradicate it.

Col. POYNDER thought the natives of India hopeless pupils in preventive measures, for they would even drink water which they had been told would cause cholera.

Mr. CANTLIE recommended the "Swatow mosquito lamp" used in China to get rid of the mosquitos within a net.

Note on the Entrance of Ankylostoma Embryos into the Human Body by Means of the Skin.—Professor F. M. SANDWITH of Cairo said that it was known that this parasite could enter the system through the mouth, but Dr. Looss has discovered that the embryos can enter the body by the skin, chiefly by the hair follicles. While conducting experiments in the laboratory of the Cairo Medical School, a drop of pure culture of embryos fell on his hand, and examining the drop a few minutes later he found that only empty embryo sheaths and a few sluggish embryos remained, the embryos having entered the skin. Local burning and redness followed, with symptoms of ankylostoma infection. Experimentation on a leg an hour before its amputation showed that the embryos entered the hair follicles, and pushed into the hair papillæ, nearly destroying the root sheath. From this point they entered the true skin.

Lieutenant-Colonel G. M. GILES, having seen Dr. Looss' specimens, could bear out the statements of Professor Sandwith, but it still remained to be shown how the ova infect the intestines in the numbers they do. The soil, especially in the tea gardens of Assam, is impregnated with these ova, and the coolies with unwashed hands eat their food, and probably take in and swallow many ova.

Dr. MANSON thought the embryo entered the hair follicle merely for shelter, but advised further research on the subject.

Causation of Typhoid Fever in India.—Dr. ANDREW DUNCAN of London first presented some of the theories that have been upheld concerning typhoid fever in India: (1) The vicarious theory of Martin, according to which insufficiency of action follows hepatic activity, inducing vicarious abnormal activity of the intestinal glands, terminating in suppurative enteritis. (2) M. Colin's transformation theory; primary paludal infection may be transformed into enteric fever, or enteric fever may be spontaneously developed from any acute febrile state. (3) Surgeon-General Moore regards no fever as specific; typhoid fever is merely a phase of fever, enteric spots merely a petechial eruption. (4) Sir Joseph Fayrer holds that climatic and telluric conditions play as large a part as fecal poisoning in the etiology of this disease in India. (5) Surgeon-General Gordon of Madras at one time advanced the theory that enteric fever did not exist in India. (6) Sir Anthony Horne holds that there are fatal cases of fever in which at the autopsy any intestinal ulcerations found should be considered typhoid. Dr. Duncan gave the factors of enteric fever in India as: (1) The yearly advent of many soldiers and others at an age most liable to the disease; (2) favorable environments for its propagation and spread. The soil of many parts of India is contaminated with Eberth's bacillus, which soldiers imbibe in the native drinks. Flies contribute to the spread of the infection. As regards prevention, the stools should be burned and the urine must also be dealt with, as it contains bacilli longer than stools. Inoculation, as introduced by Wright of Neltey, is a success, as shown by the statistics in India: In South Africa, Egypt, and Cyprus, the evidence of the prophylactic power of Wright's inoculation fluid is also apparent.

Lieutenant-Colonel A. CROMBIE believed typhoid fever to be less prevalent among natives than among Europeans. Its prevalence varied according to locality and people, it being common among the Ghoorkas, for instance, and not in Madras and Lower Bengal. As regards the Widal reaction, three natives of Bengal, under thirty years of age, living in London, and three over forty, similarly placed, were examined; those under thirty gave a well-marked reaction, although in good health and with no history of typhoid. Those over forty gave no reaction. Dr. Crombie believed that in India there are fevers running a twenty-one days' course which are not typhoid. In South Africa, seventy-five per cent. of cases returned as typhoid gave the Widal reaction. As to Wright's inoculations, among three hundred patients convalescent from fever in South Africa, sixty per cent. had been inoculated once and ten per cent. twice. One patient had the disease two months after a second inoculation, and moreover second attacks of typhoid fever were not uncommon.

Captain BALTYE stated that, in order to test the spread of typhoid, servants were made to rinse their hands in water in a common basin, but even after several days no Eberth's bacilli were found. A harmless organism may become pathogenic under such conditions as the presence of decomposing matter would engender.

Lieutenant-Colonel POYNDER thought typhoid fever a disease of youth in India, which might account for the absence of the Widal reaction in the men mentioned by Dr. Crombie, who probably had had the disease in their youth.

Professor SANDWITH, of Cairo considered the Wright inoculation method to be very incomplete as yet; when it is tried, the blood should be systematically examined. Of twelve nurses who went to South Africa three had typhoid fever, but none died.

Third Day—Friday, August 2.

Maladies of European Children in Hot Climates.—Lieutenant-Colonel A. CROMBIE, whose experience was gained in Calcutta during a long residence, thought that among the civil population the sick rate of European children is lower in India than in the United Kingdom. As to the death rate, however, that of soldiers' children in Britain is but 18.31 compared with 41.09 per thousand in India, where illnesses are therefore more fatal.

	Admission rate				Death rate				Case Mortality per cent	
	Britain	India	Britain	India	Britain	India	Britain	India	Britain	India
Eruptive Fevers	94.9	68.9	26.0	...	1.27	1.83	...	0.55	1.3	2.7
Malarial Fevers	1.7	97.3	...	95.6	0.0	2.18	...	2.18	...	2.2
Other Fevers	4.2	18.0	...	14.8	0.0	0.55	...	0.55	...	3.0
Tuberculous Disease	2.3	3.1	...	0.8	0.98	0.73	25	...	43.2	23.5
Debility, etc	18.0	38.4	...	20.4	0.98	2.36	...	1.38	5.4	6.1
Other General Diseases	27.3	17.8	10.5	...	1.73	3.45	...	1.72	6.3	19.3
Diseases of Nervous System	9.3	10.0	...	0.7	2.80	5.82	...	3.02	30.4	58.2
Respiratory "	134.9	68.0	66.9	...	4.46	6.91	...	2.45	3.2	10.2
Digestive "	103.5	96.2	7.3	...	3.71	13.09	...	9.38	3.5	13.4
All Diseases	507.3	527.1	...	19.8	18.31	41.09	...	22.78	3.6	7.8

When the cases of malaria are omitted as not being common to both Britain and India, the admission rate in India is reduced to almost 100 per 1,000 less than in the United Kingdom. Even including malaria the admission rate for soldiers' children in India is only 19.8 per 1,000 in excess of the admission rate in Britain. Measles in 1899 occurred almost as frequently among

European children in India as at home, but was more fatal in India. Scarlet fever is rare. Respiratory disorders are less frequent but more fatal than in Britain. Pneumonia is, next to cholera, the most formidable disease met with in practice in India. Diseases of the digestive system are not so frequent in India, but about six times more fatal. Dysentery is difficult to define, being often confounded with rectal catarrh; hence the cures by various specifics so often heard of. Children in India do not have liver abscess following dysentery. The term "other general diseases" in the table above, includes whooping cough, mumps, anæmia, and immaturity at birth. Rickets is uncommon among the natives, perhaps because they so generally nurse their children. Simple continued fever claims many victims. Tuberculous diseases are uncommon among children in India. Tabes mesenterica is rarely seen among natives, and of recent years European children have had it less frequently. On the whole, while European children in India enjoy a certain relative degree of immunity from some of the diseases of childhood, the death rate and the case mortality from all diseases excepting tubercle is higher among them than in the United Kingdom.

Dr. EDWARD HENDERSON had for thirty years treated many children in Shanghai, a sub-tropical climate, where the climatic changes are always well marked, and the summers are seasons of tropical heat. The effect of tropical heat on the European constitution is usually unfavorable, children suffering more than adults. During hot weather, diarrhœa, dysentery, and infantile cholera prevail, and after a hot summer anæmia and loss of tone are apparent. Heat causes enfeeblement of the nervous and muscular systems, and through these the digestive organs. It probably favors the development of the specific germs of certain diseases, and also causes decomposition of foodstuffs. Tropical heat, when long continued, causes the too rapid growth of children at the expense of general development. The cycle of nature, both animal and vegetable, is shorter in the tropics. Maturity is sooner reached, and decline hastened. At from four to seven years European children should be sent to Europe and kept there until growth is fairly completed. In the treatment of diarrhœa, drugs play a subordinate part. Milk should be stopped for several hours, and then beef juice or egg-albumen in water given, and brandy used, in some cases. Water must be freely given for thirst. Calomel in divided doses is the best medicine. Bottle-fed infants suffer from cholera more frequently than the breast-fed. Milk decomposes so easily in the tropics that it needs constant attention, and the native dairyman is not to be trusted. A wet-nurse should be provided if the mother cannot nurse her infant. The "diarrhée sudorale" of the French, in which the skin acts excessively, should be borne in mind, and the excessive perspiration should receive attention. Children should sleep on Canton matting and have a punka in the nursery, care being taken that they are sufficiently clothed and have the abdomen covered. Intestinal worms, especially lumbricoides, which are more common than in England, may cause or aggravate bowel troubles. They may exist for a long time without causing trouble. Bowel antiseptics which arrest fermentation and the astringents which pass through the stomach unchanged to act on the intestines are of great value in the treatment of diarrhœa.

Dr. MANSON asked Dr. Crombie for a definition of dysentery, and for information upon the increase of diphtheria, trismus neonatorum, and hypertrophic cirrhosis of the liver in India. He agreed with Dr Henderson regarding the advantages of breast milk and the necessity for a wet-nurse.

Major W. H. BURKE endorsed Colonel Crombie's opinions regarding the rarity of typhoid fever among natives of India. He had treated many cases of this disease among Parsees, and also among what may be called the scions of noble houses, sons and relatives of native chiefs; the Parsee has no caste prejudices and the Rajah is above them. This seemed to bear out Colonel Crombie's deductions. On the other hand, he thought there was at present an immense amount of tuberculosis among natives in Bombay, and he considered that Colonel Crombie had not dwelt sufficiently on the unhealthfulness for European children of the rainy season in India, nor on the functional weakness of the liver among European children in India

SECTION OF OBSTETRICS AND GYNECOLOGY.

Second Day—Thursday, August 1, 1901.

When and How to Operate on Uterine Fibroids.—Dr. WILLIAM DUNCAN of London opened a discussion on this subject He said that while very divergent opinions were held as regards the liability of fibroids to kill the patient, there could be no difference of opinion as to their deleterious effect on health in many cases. They had been shown to cause fatty heart, and this was a common cause of death after operations. If a woman with a fibroid became pregnant there was a serious risk of abortion, rupture of the uterus, and cerebral hemorrhage from disease of the blood vessels. Parturition was dangerous in these cases, especially when the fibroid was situated low down near the cervix. In many cases fibroids even of large size caused no trouble, and when this was the case they should not be interfered with; it was wrong, therefore, to recommend that all fibroids should be operated on. The conditions indicating operation were: (1) Hemorrhage, (2) pressure symptoms, (3) rapid growth, (4) a complicating pregnancy.

1. When there was hemorrhage he advised that the cervix should be dilated and the uterine cavity explored, and if there was a submucous fibroid or a polypus it should be removed. This should always be done before more radical operations were undertaken, otherwise a uterus might be removed containing a polypus which could easily have been dealt with by simpler means.

If after dilatation a large submucous tumor was found, what should be the treatment? He did not approve of morcellement, for if this was done and the patient subsequently became pregnant he thought there was danger from thinning of the uterine wall. The removal of the appendages had fallen into disuse, and it had been found to be better for the woman to remove her uterus and leave the appendages rather than to remove appendages and leave uterus. Apostoli's electrical method in his hands had proved a complete failure. He advocated hysterectomy. Abdominal myomectomy was the operation "par excellence" for subperitoneal fibroids, but where there was more than one tumor he preferred hysterectomy and considered the latter *the* operation for most cases. Panhysterectomy or the intraperitoneal operation might be done; tixing the stump in the wound was to be condemned. On the whole he preferred subperitoneal hysterectomy, suturing the broad ligament carefully, and he would reserve panhysterectomy for cases in which the cervix was involved by the growth. He did not practise vaginal hysterectomy for fibroids. His statistics showed 127 cases with 4 deaths.

2 Pressure symptoms affected the bladder, rectum, and sacral nerves. Sometimes one could push the tumor up and relieve pressure symptoms. When that was not possible hysterectomy was the only thing to be done.

3. When there was rapid growth it was due to cystic or malignant degeneration and always called for hysterectomy.

4. In cases of complicating pregnancy, it was not necessary to interfere if the fibroid was in the upper part of the uterus. When it was in the lower part there were three courses open, namely: (a) To empty the uterus; (b) to perform immediate hysterectomy; (c) to allow the patient to go to term and then perform cæsarean section

and hysterectomy. He would try (a) and if that failed do (b).

Technique of operations for fibroid tumors. There were two dangers: (1) Shock with heart failure; (2) tympanites from intestinal paralysis. For (1) he gave nutrient enemata every four hours, with liq. strych. hypodermically. For (2) if no flatus was passed for twenty-four hours a long rectal tube was introduced, and this was followed by a turpentine enema. He tied off the ovarian and uterine arteries before cutting the peritoneal flaps and found that there was then less hemorrhage. Oozing points in the cervix were tied with catgut and the peritoneum was stitched with fine silk by Lembert sutures. He used to cut out a wedge from the cervix and suture the muscular tissues with silk, but had abandoned that and now never sutured the cervix. In cases of burrowing in the broad ligament, after enucleating the tumor he closed the cavity by continuous pure silk suture. He sutured the abdominal wall in three layers with silk. He always left the ovaries unless they were obviously diseased.

Dr. CUTHBERT LOCKYER of London read a paper on a case of cystic fibromyoma in a single woman of twenty-three years. Myomectomy was performed and his patient recovered. The tumor resembled a six-months' pregnancy and there were uterine contractions, but not ballottement. The tumor was presenting at the os, which was dilating; it was removed by morcellement and the uterine cavity was washed out and packed. Microscopical examination showed the tumor to be a fibromyoma.

The PRESIDENT said that he would like to hear opinions on the occurrence of degenerative changes in fibroids.

Mr. ALBAN DORAN said that small, hard fibroids causing no pressure symptoms or hemorrhage should not be removed: the success of any operation did not mean its justification. Fibroids which were increasing, causing pressure symptoms, or causing metrorrhagia (to which he attached much more importance than to menorrhagia) should be removed. For shock he used liquor strychniæ also sparteine. He could not speak well of Apostoli's method—it led to adhesions and so increased the danger of subsequent operation. In pregnancy, with the fibroid in a lower part of the uterus he would operate at once and not wait for full term, but when the fibroid was in the fundus he would leave it alone. He had done twenty-nine cases since January, all by the retroperitoneal method, with one death. To prevent the ligatures working into the bladder he made a large anterior flap. He sutured the peritoneum over all raw surfaces, including the ovarian stump. He strongly advocated the ligature of the uterine arteries without transfixing the peritoneum, and thought it was better to divide the arteries and see spouting before applying the ligatures. Transfixion of the broad ligament with pedicle needles was apt to lead to injury to a vein and subsequent thrombosis. He did not find that removal of the ovaries produced such bad results as some described.

Mr. CHRISTOPHER MARTIN of Birmingham advised operation when the fibroid was rapidly growing, cystic, or sloughing, and when there was pressure on the bladder or hemorrhage in a woman under forty years of age. He had operated on seven cases of sarcoma of the uterus in which the history showed that malignant degeneration had attacked an old-standing fibroid. In operating on submucous tumors, he divided the uterus anteriorly, after stripping up the bladder to the peritoneal reflexion, and in that way found that he could remove a large mass, afterwards sewing up the incision with catgut. He approved of myomectomy in certain cases, and preferred panhysterectomy when the cervix was diseased. The great cause of shock was exposure of the intestine, and this was obviated by the Trendelenburg position. In the after-treatment of operative cases he gave fluid in fair quantities by mouth or rectum and raised the foot of the bed. His statistics showed forty-seven abdominal hysterectomies for fibroid with one death; eight for sarcoma with two deaths; thirty-three vaginal hysterectomies for fibroid with two deaths.

Dr. HAWKINS AMBLER of Liverpool thought that heart degeneration was an indication for operation. The Trendelenburg position prevented stasis in the pelvic veins and so prevented shock. Atropine was useful for shock, also nutrient enemata containing forty grains of carbonate of ammonia, as advised by Kelly.

Dr. ALFRED SMITH of Dublin agreed with Dr. Duncan as to indications for operation, but made an exception in the case of a large tumor in a single woman when the mere size of the tumor was a trouble. He used the same technique as Duncan. In very anæmic women he practised a long preparatory treatment with arsenic and iron, also did preliminary curetting.

Dr. CAMPBELL of Belfast had found that too large flaps of peritoneum allowed blood to accumulate underneath them, forming an hæmatocele.

Dr. GARRETT ANDERSON of London had seen many cases of fibroid before the days of operation, and felt sure that cerebral hemorrhage sometimes resulted from the continued bleeding leading to changes in the blood vessels. She had also seen several cases of malignant degeneration of old fibroids.

Dr. MARY SCHARLIEB of London did not believe in Apostoli's method; she thought it caused adhesions, and that, as a rule, fibroids were found to be free from adhesions. She also thought that degenerations were more frequent than usually supposed; and had found that in cases of fibroid there was nearly always disease of the appendages, and sometimes pyosalpinx. She had removed a fibroid tumor from a girl of fifteen.

Dr. STANLEY BOYD of London said that mere increase in the size of the abdomen in cases of fibroid in single women, by reason of its mental effect in some cases, justified operation. Bilateral section of the cervix to get at sub-mucous tumors was better than dilatation in some cases. She had had good results from morcellement after dividing the uterine wall.

Mr. BOWERMAN JESSETT of London said that if tumors were growing after the menopause early operation was indicated. He had seen ten cases of sarcomatous degeneration, but believed carcinomatous degeneration was rare. He had known tumors diminish in size after pregnancy.

Dr. AUST LAWRENCE of Bristol had given a prolonged trial to Apostoli's method, but had abandoned it.

The PRESIDENT said Apostoli's treatment might be put aside. The best method of operating was the retroperitoneal, tying the vessels individually. He did not approve of starving patients after operation.

Dr. Duncan, in reply, said he did not approve of Apostoli's method. He liked to make big flaps, and then to cut off the excess, so as to avoid a dead space. He preferred the retroperitoneal method to both panhysterectomy and vaginal hysterectomy.

Ectopic Gestation.—Dr. SMITH of Dublin reported a case of successful laparotomy for abdominal pregnancy, with removal of the fœtus, placenta, and gestation sac *en masse*. The fœtus was a female at full time, but dead. There was no trace of ovary or tube in the sac. The main blood supply was from the left ovarian artery.

Dr. STANLEY BOYD read a paper on "A Case of Twin Pregnancy, Extra-uterine and Intra-uterine."

Dr. HASTINGS GILFORD read a paper on ovarian pregnancy. He referred to four previous cases and gave notes of his own case.

Third Day—Friday, August 2.

The Diagnosis and Treatment of Metritis and Its Relationship to Malignant Disease.—Dr. JOHN CAMPBELL of Belfast opened a discussion on this subject. He said

that the following conditions might be mistaken for metritis:

1. Early pregnancy. The best distinguishing marks were the flattened form of the uterus in metritis as compared with its globular form in early pregnancy, and the difference in consistence; in metritis the cervix and body were about equal in consistence, whereas in pregnancy there was marked softening of the body, the cervix at first remaining firm.

2. Cancer. The hard nodules formed by the nabothian follicles and resembling cancerous nodules, disappear on pricking. He thought that the friability of the suspected tissue was the best clinical sign of cancer. When the sharp curette was used in cases of cancer, pieces of tissue came away, but in metritis only shreds. The importance of pain as a symptom of cancer had been much exaggerated in the textbooks, and cachexia only appeared late in the progress of the disease. The diagnosis rested mainly on the effect of using the sharp curette.

3. Incomplete abortion might simulate metritis.

4. Fibroids could be recognized by irregularities in shape of the uterus, and by examining the interior, after dilatation, with the finger.

5. Salpingitis, recognized by vaginal and rectal bimanual examination.

Metritis gave rise to many reflex symptoms, and these might give the case the aspect of one of tuberculosis or severe dyspepsia.

Prevention of Metritis.—The management of labor and abortion still leaves much room for improvement; it was wrong teaching that the whole uterus can be cleared out by the finger; often the finger never gets beyond the internal os; he always advised the use of the flushing curette. He thought that blunt curettes were useless. Indiscretions during menstruation were a prolific cause of metritis. Women and girls should avoid exertion at those times and use aseptic pads. Gonorrhœa was a very important cause, and in the prophylaxis of this we could not do very much.

Treatment of Metritis.—In the management of this affection we must have resort to tonics, saline aperients, and douches. For the latter not less than two quarts should be used, and the douche should be continued for twenty minutes at a temperature of 100° to 120° F., in the dorsal position, care being taken carefully to evacuate the residue.

Hip baths were of some service. The value of the tampon had been over-estimated; when used, a daily application was necessary. Local bleeding by puncture, followed by warm douche, was useful.

Intra-uterine medication could be effected by irrigation by a double catheter with or without dilatation. Plugging with iodoform gauze was suitable, especially for gonorrhœal cases. Application of solid caustics had been abandoned. Among the liquids now used were solutions of zinc chloride, carbolic acid, and tincture of iodine. He thought the application of liquified carbolic acid on a prepared probe was the best. The cautery was useless, and atmocausis was dangerous.

Curetting was the best method of active treatment, but must be followed by other treatment. He used a sharp curette. The time in relation to the period at which the curetting was done was not of much importance. General anæsthesia was optional; he had found cocaine, applied locally, efficacious.

The operation of curetting was performed as follows: His first measure was to scrub the vagina thoroughly with a toothbrush, and he then passed in a sound to ascertain the direction of the uterus. He used Duncan's long-handled dilator, and thought that extreme dilatation was unnecessary. He flushed the uterine cavity with 1:2000 perchloride solution before curetting, and after the curetting swabbed out with iodine.

Among the dangers of curetting were: (1) Perforation of the uterus; this was especially likely to arise when the direction of the uterine cavity was not borne in mind. (2) Peritonitis; this was generally due to curetting having been performed when salpingitis existed.

Further methods of treatment which had been recommended were: (1) Electricity. This was utterly inefficacious. (2) The yeast method for gonorrhœal cases, of which he could not speak, as he had not tried it. (3) Mercurial ointment applied to the endometrium was useful in venereal cases. Old standing erosions were best treated by excision of the diseased area. Caustics were useless. (4) Hemorrhagic metritis was treated by hydrastis canadensis, ergotin, and injection of perchloride of iron. Cancer of the cervix was predisposed to by lacerations of the cervix, the proof of which was its rarity in nulliparæ. Cancer of the body had been known to follow metritis.

Dr. SCHARLIEB of London thought that undoubtedly endometritis sometimes went on to cancer.

Dr. HERBERT SNOW of London thought that weakness and exhaustion were among the earliest symptoms of malignant disease, and he placed no value on the opinion of the microscopist in making a diagnosis.

Dr. AUST LAWRENCE of Bristol discountenanced the active treatment advocated by Dr. Campbell, and drew attention to the danger of bursting a pyosalpinx during the manipulations.

Dr. INGLIS PARSONS of London had found electricity useful for arresting the hemorrhage, and thought it was quite wrong to say that weakness was an early symptom of malignant disease. He agreed with Dr. Campbell that dilatation sufficient to give access to the finger was not necessary. He always found that if there was anything in the uterus the os dilated easily.

Mr. BOWERMAN JESSETT of London said that in catarrhal endometritis he would not use the curette, but preferred ichthyol and glycerin plugs.

Dr. PURSLOW of Birmingham had met with four cases in which long-continued hemorrhage had failed to be arrested by the line of treatment laid down by Dr. Campbell, and as the resultant anæmia was endangering life, he had performed vaginal hysterectomy, in each case successfully. He would like to have heard more from Dr. Campbell of the newer methods of dealing with severe hemorrhage by atmocausis, injection of gelatin, etc., as he would welcome some other method of treatment than hysterectomy.

Dr. GARRETT ANDERSON of London thought that there was risk of diffusing malignant disease when the curette was used.

Dr. SQUARE COOK of Stroud thought it was very difficult to clear out abortions with the finger, and was convinced that Dr. Snow's opinion about early cachexia in malignant disease was wrong.

Dr. STANLEY BOYD of London said that a careful examination should exclude disease of the tubes before curetting was done. Many cases of relapsing metritis were due to gonorrhœa and the discharge should be examined for gonococci.

Dr. HAWKINS AMBLER of Liverpool said that continued disinfection of the uterine cavity should follow the use of the curette.

Dr. MONTAGUE HANDFIELD JONES of London said that most cases in the early stage were cured by curetting and cleansing the endometrium. If cancer did follow metritis, there was a long preceding interval; he thought there was a danger of the curette disseminating carcinoma.

The PRESIDENT said that many cases were due to inefficient treatment of abortion. Partial detachment of the placenta was especially frequent from the twelfth to the twentieth week; the finger will not suffice to clear the uterus—we must use the curette. Cases of gonorrhœal metritis were very intractable. He believed in the application of strong nitric acid. After curetting, he used equal parts of tincture and liniment of iodine with a Braun's syringe. He placed dependence, in the diagnosis

of cancer, on the report of a microscopist who was skilled in uterine pathology.

Dr. Campbell, in reply, said that he placed much reliance on getting a plug of tissue in the curette, while scraping a suspicious area, as a sign of cancer. He had found atmocausis unsatisfactory; had had no experience with gelatin. He had found it necessary to do vaginal hysterectomy in some cases.

Prolapse of the Uterus.—Dr. INGLIS PARSONS of London read a paper entitled "Further Report on a New Operation for Prolapse of the Uterus with Notes of Forty Cases." He discussed the different operations for prolapse, and said that the best plastic operation was the one in which a triangular flap from the posterior vaginal wall was taken, and the perineum was repaired. In many cases operation failed, and in these the fault was due to the abnormal relaxation of the uterine ligaments. This alone would give rise to prolapse, as in those cases in which prolapse occurred with an unruptured hymen and relaxation was absent, prolapse did not occur even when there was complete rupture of the perineum. Ventral fixation was good for retroflexion, but of no use for prolapse, because of the drag on the abdominal wall. The band of connective tissue in the broad ligaments was one of the most important supports. His operation consisted in injecting quinine into the base of the broad ligaments so as to set up some inflammation of the cellular tissue with subsequent contraction. He used a special syringe and needle, the latter being one inch long. The strength of quinine used was 1 in 5; he kept up the uterus after injection by a cup-and-stem pessary for some weeks.

Extirpation of the Vagina and Uterus in Cases of Intractable Prolapse.—Mr. CHRISTOPHER MARTIN of Birmingham reported a case in which he had performed this operation. The patient, a widow, aged fifty-three, had previously had ventral fixation and repair of the perineum performed at one operation, and anterior and posterior colporrhaphy at a second. She had tried various pessaries, but all treatment had failed to keep up the prolapse. The operation was performed by making a posterior longitudinal incision opening into the pouch of Douglas, and a circular incision near the vulva. After the uterus was removed the peritoneum was sutured with catgut, then the connective tissue was sutured, and lastly the skin. Two years had elapsed since the operation, and the result was still satisfactory, the woman being able to get about in comfort.

Inversion of the Uterus.—Dr. HAULTAIN of Edinburgh read a paper on "The Reduction of Chronic Uterine Inversion by Abdominal Hysterotomy, with Report of a Successful Case." He opened the abdomen, made an incision through the posterior wall of the uterine cup, pushed up the fundus from below, and after reduction sutured the uterine wall with catgut. He considered it unjustifiable to remove the uterus unless it was gangrenous. He preferred abdominal to vaginal section because of (1) the smaller incision in the uterus, (2) the easier control of hemorrhage (which is very free), and (3) its greater safety.

A vote of thanks to the President, proposed by Dr. Cooke, Vice-President, seconded by Professor Wright of Leeds, concluded the business of the meeting.

Cases of Prolonged Fever, not Typhoid.—J. P. West reports a series of cases of a type apparently common in some parts of the country. They take the course of a continued fever, do not yield to quinine, do not respond to any of the laboratory tests for typhoid, and are difficult to diagnose as to their exact nature. They perhaps resemble more closely than anything else that type of malarial fever known as the estivo-autumnal. All the patients recovered, but convalescence was in each case very tedious.—*Cleveland Medical Gazette.*

BRITISH CONGRESS ON TUBERCULOSIS.

Held in London July 22–26, 1901.

(Continued from page 314.)

SECTION I.—STATE AND MUNICIPAL.

First Day—Tuesday, July 23.

THIS section was designed to interest the public almost if not quite as much as the profession, and to some extent it succeeded in doing so. It hardly was expected that many members of Parliament, wearied with the labors of the session, would take part in discussions on subjects which, if anything results from this Congress, will come before them in their legislative capacity. A number of papers upon the statistical aspects of tuberculosis will appear in the Transactions, having been prepared merely for record, not for discussion. The first of these was by Dr. Tatham, of the Registrar-General's office, who dealt with the mortality from phthisis during the last forty years, the geographical distribution of the disease, its age and sex distribution, its occupation incidence, and the evidence against its heredity.

Dr. V. Korosy, Director of the Budapest Municipal Statistics, related his observations on the influence of occupation, age, social position, the food of children, and other factors influencing the occurrence of phthisis. Drs. Chalmers and Kaye contributed other papers. All the foregoing were presented in the division of the section devoted to statistics.

President's Address.—Sir HERBERT MAXWELL spoke a few words of welcome, and then proceeded to outline briefly the work prepared for the section. Speaking of notification, he said that the enforcement of sanitary regulations was almost impossible unless the reasons for them were thoroughly understood and approved by the people. Sunlight was necessary to health, yet the tendency in cities was to shut this out more and more by increasing the height of buildings. Legislation in this matter was, he thought, of prime necessity.

The Notification of Tuberculosis.—In the second division a discussion on notification was opened by the reading by Dr. E. G. JANEWAY of a paper contributed by Dr. H. M. BIGGS, of New York, on "Notification as it is in Operation in New York and Other Cities of the United States." After a review of voluntary and compulsory notification of infectious diseases generally, he said that in 1897 the New York Board of Health declared tuberculosis to be a dangerous and contagious disease and that physicians should be called upon to report cases to the Sanitary Bureau. A sum of $60,000 was appropriated to the care of poor sufferers from the disease. The regulations were not strictly compulsory, but public opinion was gradually decreasing the number of cases not notified. The authorities examined sputa without charge for physicians. In consequence of the measures adopted there had been a reduction of thirty per cent. in deaths from tuberculous disease.

Dr. WM. OSLER moved a vote of thanks to Dr. Biggs, which was heartily carried. He said there had been great opposition to the measures of the Board of Health, but their success was an object-lesson of what might be accomplished in spite of opposition.

Alderman MCDOUGALL, Deputy-Chairman of the Sanitary Committee of Manchester, then gave an account of the working of voluntary notification in that city. At first the plan was restricted to public institutions, but in 1900 the city council invited practitioners to notify their cases, and appointed a medical man to visit and instruct as to disinfection, supervise and carry out preventive measures, and otherwise assist the medical officer of health in carrying out the scheme. The city has also begun the isolation of advanced cases from crowded houses. A new hospital has been given by Mr. Crossley, and applications for admission are numerous. The beds available for Manchester will shortly be 120 for sanatorium and

twelve for isolation apart from the provision made under the Poor Law.

Dr. HOLMBOE, Director of the Medical Service of Norway, gave an account of notification in that country, but he admitted the law was too recent to allow of certainty as to its effects, though up to the present no objections had been raised to compulsory notification on account of its inconveniences.

Dr. KNOPF of New York dealt with the State and individual prophylaxis of tuberculosis in childhood and the need of children's sanatoria. He did not believe the bacillus could be transmitted by heredity, but a predisposition might be. Practically all infection was post-natal, and the child might be infected from the earliest period, even at birth, by a careless midwife. Numerous ways in which children are liable to infection were mentioned. The duties of the State were pointed out. An urgent need for sanatoria to which schools should be attached was insisted on.

Dr. BOMPARD of Paris detailed the measures employed in France on behalf of poor town children. They endeavored to give them a sojourn in the country, and a number of municipalities had devoted money to this purpose. Paris spent 279,000 francs in this way and 4,000 children were benefited. It was estimated that a child gained two kilograms in weight and two centimetres round the chest during its sojourn in the country.

Dr. PETIT of Paris detailed the work of establishing dispensaries in that city for young patients at which 17,000 children had been treated in the last two years.

Dr. ALDERSON of Kensington said voluntary notification was not successful and the distribution of sanitary pamphlets of little use. Compulsion made all practitioners act alike. Cases discharged as cured should be reported to the medical officer of health, for relapses were common.

Dr. ROBERTSON of Sheffield had met with no difficulties as to visits of inspection of houses. But owners of workshops raised objections to sanitary cleansing. He thought the importance of healthful conditions of life and open-air treatment could not be exaggerated.

Dr. COOPER-PATTIN of Norwich always endeavored to carry out disinfection after a death from phthisis and had been able to disinfect ninety-five per cent. of houses after such deaths. He thought it hopeless to advocate compulsion unless sanatoria were provided, and it must be remembered that the contagion, if not virulent, is long continued. His committee were willing to schedule tuberculosis, but the local government board would not sanction it. He was glad to hear from Dr. Biggs that advanced Anglo-Saxon democracies were not afraid to interfere with liberty on behalf of sanitation.

Dr. STONE of Boston said that last year the Boston Board of Health included notification of tuberculosis and disinfection of premises after death in their regulations. There were public institutions for the pauper class, but others did not like to go to them, and compulsion was occasionally necessary.

Dr. HOFFMAN remarked on the absence of any scheme for including early cases in notification such as are continually being rejected for life insurance, and yet the early cases respond best to treatment.

Dr. RUATA of Perugia told how Italy had passed a law for compulsory notification of phthisis among the inmates of schools, convents, prisons, etc.; also whenever a death from the disease occurred.

Dr REYNOLDS of Chicago said that in that city they held it to be the duty of the government to educate the public on the matter. This, he thought, should be done by the press, by visits of doctors, and popular lectures. Sometimes, he said, doctors occupied the pulpits of liberal churches in Chicago on Sunday, and he thought they did so with advantage.

Dr. NEWSHOLME of Brighton considered notification in some form had advanced rapidly. Compulsory gave more satisfactory results than voluntary notification, though he admitted that at Brighton the latter worked well. Since 1893 there had been an arrangement for examining sputum for practitioners. He proposed a resolution to the effect that voluntary notification had been attended with a promising measure of success and should be extended wherever it is practicable to adopt the consequential measures.

Sir H. LITTLEJOHN seconded this, though he approved personally of compulsion and said that in Edinburgh they could not get rid of tenement-houses and must do all they could to render them more sanitary. He advocated isolating cases in public hospitals.

Sir JOHN COCKBURN deprecated the use of the word voluntary, which might discourage attempts at compulsion. Eventually the word was left out, and the resolution was carried in favor of notification simply.

Second Day—Wednesday, July 24.

The Influence of Housing and Aggregation.—The next discussion was on the influence of housing and aggregation, and a very discursive one it turned out. It was opened by Dr. HAROLD COATES, who gave an account of an investigation under the direction of Drs. Niven and Delapine. Dust was collected where it had settled naturally on floors, walls, shelves, etc., from twenty-three infected and dirty houses, and ten clean but infected houses. In the former, the bacillus was found in 66 per cent.; in the latter, in 50 per cent. Other specimens were collected, with varying results. Chlorinated lime, one and a half ounces to the gallon, formed the best disinfectant solution. But the extreme difficulty of efficient disinfection such as required to destroy the myriads of bacilli scattered on every side by a phthisical patient is scarcely appreciated at present.

Prof. v. SCHROETTER showed a spittoon made of *papier mâché*, and Dr. WALTERS described a cheaper one.

Dr. ROBERTSON read the abstract of a paper on how to attain a higher standard of lighting and cleanliness in houses, factories, etc., and the legislation desirable to promote this end.

Dr. ESPINA Y CAPO strongly urged that hygienic paper be used instead of handkerchiefs, and be at once burned. He had also much to say of spittoons, which should be combustible and renewed daily.

Dr. GARLAND, of the Post Office, regretted, in such a department with 160,000 employés, spittoons were not provided, and other sanitary measures were neglected. The French Post Office was far better in this respect.

Dr. VOLCKMAN said metal receptacles were provided in the hospitals of Norway.

Prof. RUATA said there was less tubercle among the poor Italian peasantry than in better houses. He attributed this to the freer ventilation and the open-air life.

A resolution was adopted urging upon owners of factories and workshops the necessity of free ventilation.

Other resolutions were brought forward and discussed at some length, affecting dwelling-rooms, shops, factories, etc., and recommending periodical disinfection, adequate ventilation, and legislation to secure these. Wide differences of opinion seemed to prevail as to the precise measures desirable, and the value of such resolutions, which were in the end dropped.

Control of Meat Supplies.—Mr. SHIRLEY MURPHY sketched the procedure adopted in Great Britain to prevent the sale of diseased meat, and spoke of the prevalence of tubercle in cattle and the difficulty of inspecting all meat sold.

Other speakers gave their experience on these points, and the effect of Koch's statement was naturally considered. The general view was that there should be no relaxation of preventive measures. In England and on the Continent the law permitted the slaughtering for food of animals with local tuberculosis only, but not those affected with the general disease. Details of frauds

that had been practised were related, such as could not occur in public slaughter-houses.

Third Day—Thursday, July 25.

International Aspect of Tuberculosis.—Dr. ALFRED HILLIER opened the discussion in a paper in which he apportioned credit for measures tending toward the repression of tuberculosis impartially among the several nations of the globe. Germany led in sanatoria, America in practical measures of prevention, France in the education of public opinion; England, Norway, Denmark, Italy, all had entered energetically into the contest. He suggested the formation of an international league against tuberculosis.

The subject was further discussed by Drs. Montizambert of Canada, Robinson of Maine, Hobbs of Bordeaux, Bezly-Thorne of England, and da Silva-Amado of Portugal, and at the close the following resolution was unanimously carried:

"That this section is of opinion that a permanent International Committee should be appointed (*a*) to collect evidence and report upon the measures that had been adopted for the prevention of tuberculosis in different countries; (*b*) to publish a popular statement of these measures; (*c*) to keep and publish periodically a record of scientific researches in relation to tuberculosis; (*d*) to consider and recommend measures of prevention for the guidance and information of the governments of States and local authorities. This Congress is further of opinion that such a committee should consist of representatives to be elected by the great national societies for the prevention of tuberculosis, and also of representatives nominated by various governments."

Control of Milk Supplies.—In this discussion most of the speakers dwelt more or less on the statement of Koch regarding human and bovine tuberculosis, deploring the fact that such a positive assertion had been made on the strength of such insufficient data, and suggesting various measures to undo the mischief caused by his paper.

Fourth Day—Friday, July 26.

Sanatoria.—Sir JAMES CRICHTON-BROWNE read a paper on this subject, in which he argued that this mode of treatment has largely increased the curability of phthisis, and ought to be brought within the reach of all classes of the community. For those who can pay their way there is no difficulty, but for others help is needed, and private charity can hardly suffice. Therefore, public funds should be employed for so great a benefit to the people.

Mr. BRADBROOK, Registrar of Friendly Societies, spoke of sanatoria in relation to them. He came to the conclusion that these societies would not consider themselves sufficiently interested financially to contribute to the establishment of sanatoria.

Mr. HOFFMAN, of the Prudential Insurance Co. of the United States, read a paper on the relation of tuberculosis to life insurance. He said the latter would not contribute to the erection and support of sanatoria, but they might help in the distribution of educational literature.

Dr. HAYWARD said if tuberculosis could be abolished, the average life of the population of the country would be increased two years.

Lt.-Col. MONTEFIORE and Dr. JANE WALKER continued the discussion, and at its close a resolution was passed that the county councils should provide sanatoria for the poor.

Hospitals for Consumptives.—Dr. J. E. SQUIRE said that a hospital for consumptives should be all that a sanatorium is, and more. It should have its out-patient department, separate from the wards, and should have also a home for the dying.

Drs. CALMETTE and BERNHEIM gave an account of some dispensaries in Paris, mostly connected with the large hospitals. These dispensaries provide not merely medicine, but food and clothing for indigent patients. Sanitary officers are also attached and look after the patients at their own homes. From a preventive aspect these dispensaries have been equal to or better than sanatoria.

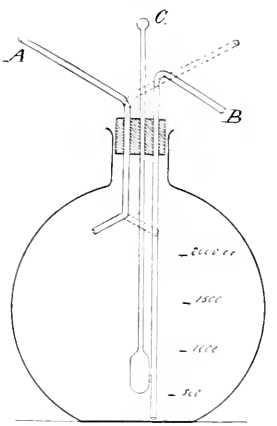
New Instruments.

A SIMPLIFIED INFUSION APPARATUS.

BY JONATHAN M. WAINRIGHT, M.D.,
SCRANTON, PA.
SURGEON-IN-CHIEF TO THE MOSES TAYLOR HOSPITAL.

IT would probably be a nearly unanimous opinion among surgeons that intravenous infusion is the most valuable single means we have for treating severe hemorrhage and shock. The very great practical difficulties in regard to proper transportation, temperature, aseptic solutions, etc., however, make this means often unavailable in private practice and in many emergencies where its use is particularly indicated. For this reason the following apparatus will be found of value to surgeons because of its portability and the ease in preparation and accurate temperature conditions of the solution which it insures. The apparatus in its present shape includes certain modifications by Dr. W. R. Munger, of St. Luke's Hospital, New York City, and has proved its value in that hospital, in private practice, and in a railway emergency hospital.

The essential part is a thin glass short-necked two-litre flask with a rubber cork perforated by three holes, one for a thermometer (*c*), another for a delivery tube (*b*), and the third for an air vent (*a*). The thermometer must register at least 200° F. The air-vent tube must have an outer arm which projects just beyond the side of the flask, and a smaller inner arm of as great a length as will allow it to pass through the mouth of the flask. The side of the flask is graduated for every 500 c.c. up to two litres with white enamel paint.



A, Air-vent Tube; dotted lines show the position to which it is twisted when the cork is inserted. B, Delivery Tube. C, Thermometer.

There is also necessary a rubber delivery tube about four feet long, to which is attached a cannula—a small-diameter medicine dropper answering very well. This tube is sterilized in the usual manner and kept ready for use in a sterile towel.

As a decinormal salt solution will deteriorate in time, it is best to keep in the flask only sterile water and add the salt at the time used. The flask then is filled with a little more than two litres of water to allow for evaporation, and this is boiled for a half hour; the tubes are then plugged with sterile cotton and rubber tissue is tied on the ends. Twelve grams of c. p. sodium chloride is similarly sterilized and preserved in a separate small bottle. In this way the ingredients of the infusion can be kept for an indefinite time ready for instant use.

To put the apparatus in action, the salt is added

and the whole is placed in hot water or over direct heat and raised to the desired temperature as indicated by the thermometer in the fluid. The delivery tube and cannula are then attached and the flask is tipped on its side so that the air-vent tube is uppermost and the water is allowed to run out of the delivery tube till syphonage is established, when the flask is righted and placed on a convenient object above the patient ready for delivery.

For transportation, a circular tin box can be made just large enough to contain the flask. In the top of the box around the neck of the flask are placed the rubber tube in its sterile towel, and the bottle of salt solution, a scalpel, forceps, scissors, and an aneurism needle (if not carried in an instrument case), so that the complete outfit for an infusion in a private house can be carried in a box much smaller than that required for a silk hat.

The advantages of this apparatus are that it is easily portable and that the solution can be prepared for use in a very few minutes, or during an operation can be kept heated and used at any moment. The strength of solution, temperature, quantity, and rate of flow are under exact control of the operator. The fluid is delivered from the vessel in which it has been boiled, and thus rubber bags or unsterilizable jars are avoided, and there is no changing from one vessel to another with the consequent delay, exposure to germs, and loss of heat.

All but the tin box can easily be made by the surgeon himself. It will add but little to the bulk of his equipment, and will prove an invaluable addition in many cases when he is called to a severe operation or obstetrical case, or in answer to an accident call.

The apparatus contains no original devices, but is simply the application of well-known principles to the end in view.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 24, 1901.

	Cases.	Deaths
Measles	72	5
Diphtheria	102	24
Laryngeal diphtheria (croup)		
Scarlet fever	93	11
Smallpox	18	8
Chickenpox	4	—
Tuberculosis	222	138
Typhoid fever	64	16

Types of Indigestion and Their Wide Correlations.—W. H. Pearse has made a study of fifty-four cases of indigestion seen in dispensary practice in the course of five years. He notes that pain may be referred to the epigastrium, back, left infra-axillary region, sternum, etc.; may come immediately after eating, or not till one hour after, may last only a little while, or be practically continuous. Vomiting was present in thirty-four of his cases, fourteen patients showed well-marked neuroses or neuralgias; two were anæmic; one had urticaria, and five had a family history of phthisis. Menstruation was normal in twenty-two (all the fifty-four patients were women), absent in four, scant in four, profuse in one, congenitally absent in two. The bowels were costive in twenty-nine, extremely so in two, and natural in thirteen.

In thirty-four of his cases of indigestion, he began treatment with muriatic acid, quinine, and pepsin; the greater proportion did well, but in thirteen of the above he had to abandon the treatment and to give bismuth, sodium bicarbonate, and lactopeptine; even then, in several, he failed to give relief. Malt extract was given under both classes of treatment. In eleven, he began with and continued the bismuth treatment. He had seen, in a few cases, rapid relief under both the acid and the bismuth treatments, but in some cases there was much failure to relieve the patients. A paramount aim was to stimulate the whole prime vie by a pill of aloes and iron or by a mineral water, by a digestible but varied diet, and by the use of lemon juice as a drink. In a few that he kept on an exclusive milk diet, temporary benefit was noted, but in general the patients were not cured by a milk diet, the relief of the pain being for a week or two only. He inclined more to a light and varied diet—fish, the best vegetables, and fruits—and was sure that lemon juice, drank daily in cold or warm water, was a good thing for both young and old.—*Medical Press and Circular.*

Inoculation as a Preventive against Typhoid Fever.—The article of H. M. Cullinan is based upon inoculation observations made in an institution for insane women. Out of 655 who were liable to be attacked, 54 contracted the disease, *i. e.* 8.24 per cent. Of 511 patients inoculated, 7, *i. e.* 1.36 per cent., were attacked after the operation. Forty-seven cases occurred in those who had not been previously inoculated, *i. e.* in 7.16 per cent. of the total number liable to infection.—*Dublin Journal of Medical Science.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 24, 1901:

SMALLPOX—UNITED STATES AND INSULAR.

		CASES	DEATHS
California, San Francisco	Aug. 2d to 11th	2	
Georgia, Pickens Co	July 1st to Aug. 10th	37	
Illinois, Chicago	Aug. 10th to 17th	1	
Massachusetts, Boston	Aug. 10th to 17th	2	
Nebraska, Omaha	Aug. 3d to 10th	1	
New Jersey, Jersey City	Aug. 11th to 19th	1	1
Newark	Aug. 10th to 17th	4	
New York, Elmira	Aug. 3d to 17th	4	
New York	Aug. 10th to 17th	36	
Pennsylvania Philadelphia	Aug. 10th to 17th	6	1
Pittsburg	Aug. 10th to 17th	2	
Utah, Salt Lake City	Aug. 10th to 17th	4	
Washington, Tacoma	Aug. 4th to 11th	1	
Philippines, Manila	June 22d to July 6th	1	

SMALLPOX—FOREIGN.

Austria, Prague	July 27th to Aug. 3d	1	
Belgium, Antwerp	July 27th to Aug 3d		1

THE WORK OF THE SANITARY DEPARTMENT OF HAVANA; WITH SPECIAL REFERENCE TO THE REPRESSION OF YELLOW FEVER.

BY W. C. GORGAS, M.D.

MAJOR AND SURGEON, U. S. A.; CHIEF SANITARY OFFICER, HAVANA, CUBA.

THINKING that some description of the sanitary conditions in Havana might be of general interest, I have prepared the following sketch of conditions as they were at the time of the occupation of the island by the United States, and of the methods instituted in the endeavor to better them. This description applies more particularly to Havana, as I personally have been connected chiefly with the work in this city.

When the Army administration took charge in January, 1899, the city had just come through a siege of several months. War had been going on in the island for five years; and under the Spanish policy of reconcentration, many of the people of the rural districts had been forced into the city, no provision having been made for their care and support, the people themselves being entirely without means. For a considerable time no attempt had been made at street cleaning, removal of garbage, etc. The American administration at once went to work and organized departments for street cleaning and disposal of garbage, and a Sanitary Department for the improvement of the general health conditions of the city. Probably the best idea of the conditions can be given by quoting the death-rate for the last year of Spanish occupation, 1898, and the two succeeding years of American occupation, these being respectively, 91.03, 33.67, and 24.40.

My personal connection with the Sanitary Department commenced in the spring of 1900, having been appointed Chief Sanitary Officer in February of that year.

The basis of the work of the Sanitary Department is the constant house-to-house inspection and supervision of the internal sanitation of the houses. For this purpose, the city is divided into twenty inspection districts with an inspector in charge of each district. This inspector is every day assigned a certain number of houses, about which he is required to make a report on a printed form. Based on this report, orders are given, principally with regard to cleaning, whitewashing, etc., and, when necessary, with regard to the more permanent improvements of plumbing, etc. This inspection report is filed in the office, each house in the city having a separate envelope in this file. The order is also filed in this envelope.

At the end of each week, in cases in which orders have been given, a re-inspection is made. The inspector reports in writing the result of this re-inspection; and if the work ordered has not been begun, the responsible party is notified that legal proceedings will be instituted. At the end of another week, a second inspection is made; and if the work is still not commenced, legal proceedings are started. If the work is even then not done, the city does it at its own expense and charges the cost against the property. In cases that are pressing, such as unusually dirty tenement houses or similar places, the department puts in its own force and thoroughly cleans and disinfects the premises. For this purpose we have a force of sixty men, divided into two squads, under the charge of inspectors and foremen; besides smaller squads for two of the suburban towns. All infectious diseases are required to be reported to the Sanitary Department by the physician in charge, under a severe penalty for non-compliance; and the premises in all infectious diseases are carefully disinfected and cleaned as soon as the case is disposed of. For this purpose we have three squads of twelve men each, under the charge of competent inspectors, and furnished with the necessary apparatus.

The method of disinfection is washing the walls and floors with a 1 : 1,000 solution of bichloride of mercury. The rooms are then carefully closed and cracks sealed, and formaline gas is used, a liter of forty per cent. formaline solution to 1,000 cubic feet of air space.

This is done for all cases of tuberculosis, typhoid fever, smallpox, yellow fever, leprosy, glanders, and diphtheria. The Sanitary Department has a well-equipped hospital for the reception of contagious and infectious diseases. All cases of smallpox are sent to this hospital; cases of leprosy to the Lazaretto; yellow fever cases are not required to go to the hospital when they can be properly isolated at home.

Naturally, the Sanitary Department has paid most attention to the question of yellow fever. The recent demonstration that this disease is conveyed by the mosquito has made a total change in the sanitary treatment of yellow fever between last year and this. Last year when a case of yellow fever was reported (and this was done on a blank form furnished by this department), a guard was sent to the apartments and the patient was strictly quarantined, no one but the physician and inspectors being allowed to come and go. After the case was disposed of, the apartments were disinfected as above described. This method only killed the mosquitos in the apartment in which formaline gas was used, and the insects had an opportunity of escaping during the ten or twelve days during which the patient was sick.

It was soon found that there was a great discrepancy in the character of the cases called yellow fever, some physicians calling all their cases of fever among non-immunes yellow fever; others making a diagnosis of yellow fever only in the most severe cases. To arrive at some common basis of diagnosis, a Board of Examiners consisting of four physicians who had the confidence of the community for ability in this respect was appointed, to whom all cases suspected of being yellow fever were referred. This,

I think, has been one of the most useful measures adopted. It has given a common basis of diagnosis and great moral support to the Sanitary Department in enforcing fines for non-compliance with regulations as to reporting cases.

When the work of the Army Medical Board became known, demonstrating the fact that the mosquito conveys the infection of yellow fever, General Leonard Wood, the Military Governor, directed that the method of disinfection for yellow fever should be based on this theory, and on the 16th of February an order was issued changing the method of disinfection in accordance with these views.

At present, when a case of yellow fever is reported, the Chief of the Disinfection Department is at once notified, goes to the house, requires those interested to designate the apartments in which they desire to be quarantined, and these apartments are then fitted with wire screen doors and windows, which make them absolutely mosquito-proof. In this way it is hoped to keep mosquitos already infected within the quarantined area, and to prevent any outside mosquitos from getting in. Ordinarily within two hours after the report reaches the Sanitary Office the apartments are thoroughly screened. A guard is placed at the house to see that unauthorized persons do not go into the quarantined area, that care is used in going in and out of the door, and that the sick-room hygiene is observed. The patient is allowed to designate three or four immunes who can go and come within reasonable limits. At the same time that the screens are put up, the disinfecting squad proceeds to kill the mosquitos in the rest of the building. Every room is carefully gone over, sealed and pasted, and pyrethrum powder is burned at the rate of a pound to 1,000 cubic feet of air space. As the pyrethrum powder, even in this large quantity, does not certainly kill all the mosquitos, the room is opened at the end of three hours and the mosquitos on the floor are swept up and destroyed. At the same time, the three or four contiguous houses are gone over in the same way with pyrethrum powder, with the idea that any infected mosquitos that have escaped from the infected building may be caught in this way.

Pyrethrum powder is generally used from the fact that it injures no fabric, is not particularly disagreeable, and creates very little opposition on the part of the people. The object of the department is to get every case that is at all suspicious reported, and with this object in view all our measures are adopted with regard to causing as little trouble and inconvenience to the people as possible. Taking all things into consideration, we have found pyrethrum powder by far the best substance for general use. Where there is nothing that can be injured by sulphur, we use this substance. Since work on this plan was commenced, we have averaged about 150 pounds of pyrethrum powder to the case.

This is the method of disinfection for individual cases, based upon the supposition that the disease is transmitted by the mosquito, that comparatively few mosquitos are infected by the individual patient, and that these mosquitos do not wander far from the point of infection. Our results, so far, seem to support this idea of the propagation of the disease.

I append tables of the deaths and cases of yellow fever occurring in Havana subsequent to the year 1889:

CASES OF YELLOW FEVER IN THE CITY OF HAVANA,

During the years 1899 and 1900, and part of 1901.

Months	1899	1900	1901
January	2	19	24
February	0	17	8
March	2	11	4
April	5	5	2
May	2	5	4
June	4	19	0
July	6	96	4
August	34	219	..
September	54	269	..
October	63	308	.
November	42	214	.
December	70	62	.
Totals	284	1,244	.. .

The cases can be given only since the American occupation, as no record of cases was kept before that time. The system of registration of deaths in Havana, since 1889, has been a very good one, and rigidly enforced; and the figures in the table below I believe to be entirely trustworthy. It will be seen from this table that, for the last twelve years, there has always been more or less yellow fever in Havana, and all data go to show that the same condition of affairs has existed since about the year 1761.

The yellow-fever year in Havana really begins April 1st. During January, February, and March, the yellow fever of the preceding year is declining, and reaches it minimum April 1st. From this date it slowly begins to increase again. The reason for this is obvious, the cool weather during winter having a tendency to decrease the causes of infection. By the 1st of April the full results of this cool weather are felt, and warm weather is beginning to commence again, so that the infection slowly revives.

The best idea of the great difference between this year and preceding years, so far as yellow fever is concerned, can best be seen by taking the five

DEATHS FROM YELLOW FEVER IN THE CITY OF HAVANA.

June	38	41	13	69	31	10	46	174	3	1	8	0
July	67	66	27	118	77	88	116	168	16	2	30	1
Totals	145	123	56	222	130	122	206	531	26	6	44	2

The average number of deaths from yellow fever in Havana for these months was 146.5; the maximum (in the year 1897) was 531, and the minimum in 1901, when for these five months we had two deaths, one in March and one in July. This is so great a difference in the amount of yellow fever, compared with anything that has gone before, that I cannot but attribute most of it to the methods of disinfection that we adopted about the middle of February for the extermination of infected mosquitos. Granted yellow fever in a locality, then the greatest factor in its variation from year to year is, I think, the number of non-immunes present who are capable of having the disease. In 1901, we probably have as many of these as at any time in the previous history of Havana.

During the year 1899 we had 284 cases with 103 deaths. The same system was continued during 1900, though it was much better organized and more efficiently carried out. We had, during the year, 1,244 cases and 310 deaths. The immigration that year, as the table shows, was unusually large.

In 1901, we began, as usual, with the yellow fever left over from 1900. In January, we had twenty-four cases and seven deaths; in February, eight cases and five deaths. About the middle of February our new plan of disinfection and destruction of mosquitos went into effect. In March, we had four cases and one death; and from the 8th of March to the 1st of August, we have had only one death in Havana from yellow fever. It will be seen from the table that we have gone five months with only one death, and with only a few cases during that time. During the month of June, we had no cases and no deaths; and during July, only four cases and one death. This is entirely exceptional, as June and July are months in which we always have a good deal of yellow fever: and is so very much better than anything else that has gone before, that I must attribute part of the result at any rate to the fact that we have at last discovered the true cause of yellow fever, and have adopted a practical means of fighting it.

TABLE OF IMMIGRATION SINCE 1890.

Number of immigrants arriving in Havana from September, 1899, to July 1, 1901—42,668.

The table of immigration shows that, since September, 1899, when a census was taken, 42,668 immigrants arrived at the port of Havana. The records of the Immigration Bureau show that sixty per cent. of these remained in the city of Havana; and only 1,535 of these have been immunized by attacks of yellow fever since that time; so that there must now be in the neighborhood of 24,680 non-immunes in the city.

The year 1899, the first of the American occupation, is the only year that approximates 1901 in the yellow fever conditions for these months. During this time, for that year, we had six deaths from yellow fever, just three times the number we have had for 1901. I have no doubt that some of this improvement was due to the great sanitary change made by General Ludlow in the first six months of his administration; but most of it, I believe, was due to the fact of the small number of non-immunes in the city during the first six months.

During 1898 and the early part of 1899, as the result of the blockade and the war, immigration had almost entirely ceased. By August, 1899, a considerable non-immune population had accumulated, as will be seen by referring to the table; and about this time yellow fever commenced to increase.

While, of course, the general sanitary conditions of the city are greatly improved each year over the preceding year, there is not sufficient difference between this year and last to account for the great improvement in the yellow fever conditions, and I think it a fair deduction to attribute the present exceptional conditions, in great part, to our killing the infected mosquitos and to the war against mosquitos generally, and this is more particularly the case as we study the sequence of cases this year.

We commenced our war against mosquitos about the middle of February. After that time we had a case on the 22d, another on the 23d, another on the 27th; and in March, one on the 2d and one on the 8th. We were apparently successful then in having killed off all the infected mosquitos. We then went from March 8th to April 20th with no

cases of fever. This was an unprecedented stretch. On the 21st and 22d of April, we had two more cases; and we were again apparently successful in getting rid of the infection. We were then free till May 6th. On May 6th and 7th we had four cases. We were again apparently successful and had no more cases originating in Havana till July 1st.

During the later part of June, a focus of infection developed in a small town about twelve miles from Havana—Santiago de las Vegas—and since that time we have gotten seven cases in the city from this point. Regla, a small town across the bay, and Cienfuegos, a town on the southern coast, in railroad communication with Havana, have also recently had cases of yellow fever. As these towns have intimate railroad communication with Havana, it makes it very difficult for us to keep infection out of the city; but having apparently been so successful in the last five months in getting rid of the foci as they appeared, we approach the present infection with a great deal of hope for success.

Since the 8th of March we have had two distinct outbreaks, separated by considerable intervals, which were apparently stamped out.

Havana has no general sewer system, and every house in the city has a cesspool. These cesspools, being protected, dark, and warm, breed mosquitos in great numbers all the year round.

The Stegomyia breeds principally in pure water, and does not appear in large numbers till the warmer weather comes on. The general water supply in Havana is excellent, coming from a large spring some miles out in the country; but the water is very hard, so that almost all the houses have some means of collecting rain-water for washing purposes; and the poor collect it in water barrels. In many of the tenement houses there will be as many water barrels as there are families, and at this time of the year most of these are full of larvæ of the Stegomyia.

With this condition of affairs in view, the Mayor issued an order that all fresh standing water should be kept either in mosquito-proof receptacles or covered with crude coal oil, and that crude coal oil should be thrown into all cesspools once every two weeks, and all yards be kept drained and as dry as possible. This order was widely distributed, and the reasons for the order were explained in simple language so that they could be understood by all.

To see that this was carried out, the city was divided into eight districts; and these districts are regularly inspected, a certain number of houses being assigned to each inspector for each day. It is arranged so that the whole city is gotten over once a month. On the reports of these inspectors, men with cans of oil follow, put oil into the cesspools, and report where drainage is necessary. If water is found in barrels not made mosquito-proof according to the order, the water is overturned and the receptacle is destroyed. We have forty men employed in this work, and use about 2,000 gallons of oil a month.

We have another division of fifty laborers, under a different superintendent, whose duty it is to do the draining. These men are at work principally in the suburbs, cleaning ditches and ditching low grounds, and trying in every manner to do away with all stagnant water. Where it cannot be drained away, it is kept oiled. The general consensus of opinion seems to be that we have been very successful in decreasing the number of mosquitos, and that they are markedly less this year than ever before.

At any rate, with conditions favorable to yellow fever, there being a very large non-immune population in the city, and yellow fever having been introduced into the city on a dozen different occasions, we have so far managed to keep it out later than has ever been done before. And even if we have fever later in the season, I feel confident that the destruction of the mosquito is the proper method for fighting the disease, and that we shall be eventually successful on these lines.

A PERSONAL EXPERIENCE IN RADIOGRAPHY,

TOGETHER WITH THE TECHNIQUE OF STEREOSCOPIC RADIOGRAPHY.*

By ALEXANDER B JOHNSON, M.D.
NEW YORK

The Use of the Fluoroscope in Surgery.—The fluoroscope appears to be a very valuable aid to the medical man, in the diagnosis of diseases of the chest, but in surgical cases it has, at least in my hands, proved rather unsatisfactory and disappointing.

For the rough diagnosis of fractures, for the detection of foreign bodies when not situated in the thicker portions of the human body, it answers well, but the practical difficulties in its use, notably in cases of fracture attended by considerable effusions of blood, the faint and feeble character of the image seen upon the screen, and the marked distortion of the shadows, which, under many conditions, it is quite impossible to avoid, together with the utter uselessness of attempting to recognize lesions of bone covered by thick layers of soft parts and encased in splints of uneven contour, place a rather narrow limit upon the value of the fluoroscope in surgery. It is true that devices now exist whereby, with the aid of two tubes, a stereoscopic picture may be seen upon the screen, and I am told that another device is being constructed at the present time which, by means of a single tube, with two anti-cathodes and a rotating diaphragm, produces a stereoscopic image. While these devices will no doubt improve the quality of the picture, it is scarcely possible that they can take the place of radiographs. For the use of the fluoroscope in general, two things are requisite: First, a steady illumination; second, a tube of rather high vacuum and great penetration. And it is worth remembering that a tube suitable for a fluoroscopic examination of, let us say, the adult knee-joint would be quite useless for the production of radiographs showing much detail and slight differences of density.

The Technique of Radiography.—The strictest attention to details, from first to last, is necessary in order to produce uniformly good results. The operator must, of course, become thoroughly familiar with every part of the apparatus under varying conditions. This is particularly the case with regard to x-ray tubes, and he who purchases two or three of the best tubes obtainable, learns to know for what purposes each one is best suited and guards them with care from accidental injury, will soon learn to know, from the mere appearance of the tube, while illuminated, what sort of a result is likely to be produced in the way of a picture in a given time. Several important mechanical details must be studied, and, as far as possible, the relation of the tube to the plate and to the part to be pictured should be reduced to some definite system. It will be remembered that, as far as is

* In order to bring this paper within the limits of a journal article, it has been necessary to omit a description of the apparatus employed. This quite important section will, however, be incorporated in the reprints which those interested may obtain on application to the author or may consult in the medical libraries

known, the *x*-ray may be assumed to proceed from the center of the platinum anti-cathode in straight lines in all directions from a point or focus upon its surface. There follows the well-known rule also applicable to ordinary light-rays, that the intensity of the illumination of an object varies inversely as the square of its distance from the source of light. When applied to radiography, this physical fact is important to bear in mind, *e.g.* if a good radiograph of a given part can be obtained at a distance of, say, twelve inches in one minute, at a distance of twenty-four inches, an exposure of four minutes will be required to produce the same result. Since in practice it is necessary, on account of the varying thickness of different parts of the body, to vary also the distance of the tube from the plate between limits which may reach from twelve to twenty-four inches or more, this difference in time of exposure becomes a very important practical detail. In fact, to determine the proper time of exposure for a given case, in order to produce a negative having certain definite qualities, is the most difficult question which the *x*-ray operator has to answer. Inasmuch as many of the problems which are to be solved do not admit of answers which can be measured mathematically, the elimination of this single error of the relation between distance and time is a matter of a great deal of consequence. I have prepared a table of comparative times and distances, based upon an exposure of ten seconds at a distance of ten inches, and have calculated the additional time necessary for all distances from ten to twenty-four inches, and from ten seconds to seven minutes. I find this table a useful aid for reference. In the effort to formulate a general rule for the duration of exposure for the production of radiographs, Donath ("Die Einrichtung zur Erzeugung von Roentgen-Strahlen," Berlin, 1899) has constructed a table upon the following basis: It is assumed that the various parts of the body possess a power of absorbing *x*-rays, which varies directly as their density, and, if the absorbing power of the middle hand through the metacarpal bones be taken as the unit of measurement of this quality, experiment and calculation give the following values for the absorbing powers or resistance to the passage of the rays of the different parts of the body.

	RESISTANCE
Hand	1.
Forearm	1–4
Elbow	1–5
Upper arm	1–8
Shoulder-joint	3.
Collar-bone	2–7
Neck	3.
Skull	4–5
Thorax	3–4
Sternum	3–8
Foot	1–4
Knee	2.
Leg	1–8
Thigh	3–5
Hip-joint	5–6
Pelvis	8–16

Donath has also constructed a general formula for the determination of the proper time of exposure in any required case. The formula is based upon the above relative table. The terms are:

a=the distance of the tube from the plate in the radiograph of the hand.

b=the distance of the tube from the plate in the picture which is about to be taken.

x=the proper time of exposure sought.

z=the time of exposure necessary to produce a radiograph of the hand.

w=the resistance of the part of the body which it is proposed to take, compared with the resistance of the hand. (This number is, of course, taken from the table of relative resistances.)

The formula then reads:

$$x = z \frac{(b)^2}{(a)}$$

While I have not made practical use of this formula, I fear that individual variations in the densities of the different parts of the body might sometimes render it inaccurate. It is necessary, of course, in every case to establish the unit, *i. e.*, the time required to take a picture of the hand; but a slender hand is often present in an individual whose abdomen is unusually thick; and a heavily-boned limb is not infrequently seen attached to a comparatively thin trunk. It will be found also that a slight change in the term *w* produces a considerable change in the term *x*.

In addition to the variation in time for distance, the much more difficult problem remains to be solved of estimating the various degrees of penetrability for limbs of different thickness and for individuals of different ages. The tissues of children are far less dense than those of adults, and require a much shorter time even for a given thickness of tissue. The tissues of women are more pervious to the rays than are those of men, and require a shorter exposure. To estimate the relative values of these different factors requires the judgment born of experience. To lay down even an approximate rule appears to me quite unprofitable, on account of the extremely varied character of the apparatus used, and the variations of the same apparatus under different conditions. With the apparatus which I possess, I use chiefly two tubes for different sets of cases. For all parts of the body thinner than the hip-joint I prefer the Queen self-adjusting tube with an extra heavy platinum anode. This tube permits me to use somewhat less than half the total practicable energy of my coil. This represents a heavy stream of sparks, ten and one-half inches long, measured on the parallel spark-gap of my coil and the No. 16 platinum wire of the Wehnelt interrupter, protruded four millimeters into the acid. To obtain the greatest amount of detail in my pictures of the thinner part of the body, I use with this tube a vacuum which corresponds to a resistance equivalent to from two and one-half to three inches, measured on the spark-gap of the tube. The current used is the 110 volts direct street current, and from four to five ampères. This gives rather a black picture of the hand in the fluoroscope. The bones appear very dark and the soft parts somewhat lighter—but still not very light. The tube, in this condition, would not be suitable for a fluoroscopic examination of the bones of the leg nor even for the elbow-joint in the well-developed male subject. When using this tube for a radiograph picture of the knee-joint of a well-developed adult, I increase the spark-gap of the tube to three and one-half or four inches. This gives a bright, clear picture of the hand in the fluoroscope, and in this condition the tube would be suitable for the fluoroscopic examination of the adult elbow and for a moderately well-developed leg. The necessary times of exposure to produce radiographs with this tube are about five times as great as with the cold-water tubes of Dr. E. Grünmach, about to be described. This cold-water tube is intended to be used on a coil giving a spark-length of sixteen inches. The penetrating and photographic power of this tube far exceeds that of any other with which I am acquainted. It can be used with an amount of energy equivalent to a very heavy stream of sparks fourteen inches in length for from three to four minutes continuously, without any

serious change of vacuum. If the current is kept up for longer than four minutes the anode becomes heated to a dull red heat, and the vacuum falls a little, but upon turning off the current the tube recovers itself almost completely in two minutes.

With this tube, using a vacuum representing a resistance equal to from eight to ten inches of spark-length upon the parallel spark-gap of the coil, it is possible to take fairly good radiographs of the thicker portions of the extremities in an astonishingly short time. A fair radiograph of the hand and forearm may be taken with an exposure too short to measure—practically instantaneous. The knee-joint may be exposed for ten to fifteen seconds with fair result. I have taken a very good radiograph of the spine, pelvis, and both hip-joints of a well-developed boy, ten years old, in thirty seconds. The amperage of the current used under these conditions was between seven and eight amperes. Even shorter exposures than this are said to be sufficient. But in practice I find that pictures showing more detail and slighter differences in density can be produced by a different method; *i. e.*, by reducing the resistance of the tube and its vacuum to a degree equivalent to from three to four inches upon the spark-gap of the coil. When used in this way, the tube gives a fluoroscopic picture of the hand which is clear, but fairly dark. And yet, with the tube in this condition, my best radiographs of the spine and pelvis of adults have been obtained. The exposures necessary to produce strong negatives are as follows:

Adult hand and wrist, distance of tube from plate, 13½ inches, 10 seconds.

Adult elbow, distance 16 inches, time 30 seconds.

Foot and leg, 16 inches, time 45 seconds.

Knee-joint, distance 18 inches to 2 feet, time 2 to 2½ minutes.

Shoulder-joint, 21 inches to 2 feet, 2½ minutes.

Thorax, distance 2 feet, 3 minutes.

Adult hip-joint, pelvis, spine and kidney regions; females, 4 to 6 minutes; males, 6 to 8 or even 10 minutes; distance 24 to 26 inches or more.

I do not find, however, that it is possible with this tube to get pictures showing such slight differences of density as with the Queen self-adjusting tube, before described. The farther away the tube is placed from the object to be photographed the less the distortion of the picture. In the case of the thinner parts of the body, this distortion is only slight when the tube is placed, say, fifteen or sixteen inches from the plate, but when a picture is taken of the hip-joints, including the pelvis of an adult, and the tube is placed in the middle line of the body, unless the distance of the tube from the plate is more than two feet, the distortion is great. The practical lessons to be drawn are, that it is advantageous to place the tube as far away from the body as is consistent with a reasonable time of exposure, and in all cases involving an exposure or exposures in the aggregate of five minutes or more, to lessen the risk of dermatitis by anointing the patient's skin abundantly with some greasy preparation—lanolin, for example—and by placing between the tube and the patient a grounded screen, consisting of thin cardboard, or wood, coated with gold foil, or with a thin sheet of aluminium. Whether these measures are an actual protection against burns or not, I am unable to say, but it is probable that they do serve to lessen the likelihood of a subsequent x-ray burn, to some degree at least. When using powerful tubes with a current of great frequency of interruption, high intensity, and considerable amperage, the possibility of producing x-ray burns, when taking pictures involving several minutes of exposure, should never be lost sight of. The danger is a very real one. If the operator will keep an accurate record of all the conditions under which each x-ray picture has been taken, he will gradually accumulate a very valuable series of data. Such a record should include the part of the body, the age of the patient, the quality of his tissue, whether fat or lean, flabby or firm, whether large-boned or delicately built, the distance of the tube from the plate, the particular tube used, the resistance of the tube, during the time of exposure, measured on the spark-gap of the coil, the fluoroscopic picture of the operator's hand during the time when the picture is taken, the position of the rheostat lever, the distance to which the platinum wire of the Wehnalt interrupter was protruded into the acid while the picture was taken, the kind of plate used, the kind and strength of the developer, the time of development, and the general character of the negative.

Any examining table of firm construction answers very well for taking x-ray pictures. It is convenient to use a table, the three sections of which may be tilted at various angles so that certain of the patient's muscles may be relaxed as he lies upon the plate. In this way it is often made more easy to keep the part to be pictured quiet and in firm contact with the plate and the patient comfortable during the exposure.

The device which I use for holding the tube is made in the form of a gallows. The vertical arm of the gallows is firmly clamped to any desired part of the table, and slides up or down, vertically, in a suitable frame. The distance of the surface of the anti-cathode from the plate is marked in inches on this vertical arm.

The horizontal arm extends over the table; it is also graduated in inches. The construction of this gallows is of wood, heavy and solid, to prevent vibration.

Upon the horizontal arm there slides a heavy wooden clamp, which hangs vertically downward. Its jaws are arranged to hold the tube horizontal, the long axis of the tube and the table parallel.

The tube can thus be moved horizontally or vertically a measured distance, and is held by suitable locking screws, quite immovable, if desired.

It is convenient to lead the wires from the coil to the tube over a light stand or framework of wood, which may be elevated to a position several feet above the patient's body. In this way accidental shocks are prevented, and the patient is less likely to disarrange the apparatus during clumsy efforts to get on or off the table. The operator is also enabled to walk all around the table underneath the wires, in order to make such adjustments as are necessary. The body of the patient should be placed upon the table in such a position that the part which it is desired to show upon the plate with the greatest clearness lies vertically beneath the center of the anti-cathode. For the determination of this relation a plumb line is useful. The patient must be made comfortable by means of pillows and blankets, so that no part of the body is in a condition of muscular tension.

That surface of the limb or trunk nearest to which the lesion is supposed to lie is placed next the plate.

Some ingenuity in arranging the patient is required at times.

In determining the question of the distance of the tube from the plate, it is a good rule to follow not to put the anti-cathode nearer than twelve inches from the skin, and for long exposures a distance several inches greater should be chosen.

The time of exposure for the given case will depend, as has already been remarked, upon a num-

ber of different factors. A high vacuum tube admits of a short exposure, but the negative produced will show but little detail. A low vacuum tube, even with the same current, will require a longer time, but will produce a negative showing far more detail, and will exhibit much slighter differences of density. Thus, if the question to be answered is merely, what is the extent of deformity in a case of fracture? the diagnosis of fracture being evident by ordinary means of examination, or if it is to be determined whether or not a metallic foreign body is present, a high vacuum tube with a short exposure answers well. If, however, the question relates to the presence of a calculus, renal or other, to disease of bone, or to pathological changes in the blood vessels, or if, in the case of a tumor, it is supposed that the mass consists partly of bone and partly of softer structures, or in any case in which it is desired to show the greatest possible differentiation of density, a low vacuum tube should be used of just sufficient penetration to furnish a strong negative after a reasonably long exposure. I have already given the results of my own experience, but the reader will remember that the time of exposure varies much with different forms of apparatus.

And a certain amount of experimental work is necessary to determine the efficiency of any particular set of apparatus. The more powerful the coil, the larger the energy of the secondary discharge; and the greater the capacity of the tube to endure a heavy current for a long time, the shorter the exposure.

The time of exposure having been settled, the plate is to be inserted beneath the part to be taken. In order to avoid the danger of the pressure of bony parts upon the glass, producing a fracture of the plate, it is desirable that some protection against this accident be used. For this purpose the plates in their envelopes are inserted, one at a time, into a shallow wooden drawer-box, not unlike in appearance an ordinary plate-holder. The box has a solid bottom of wood, bearing upon its upper surface two brass springs, which serve to keep the plate in contact with the top of the box. The cover or top may be made of any light fairly rigid material pervious to the rays. Mine are covered with a very heavy stiff paper or fibre board.

The space between top and bottom is open at one side of the box; and the space is wide enough to permit a plate in its envelope to be easily inserted and removed.

It is convenient to have these holders of several sizes. For plates as large as 14 x 17 I use a broad framework of planking, across which there slides a long and shallow wooden drawer, above which is a stiff paper cover. The patient lies down upon the paper cover, a plate is inserted, and the drawer closed. After the exposure is made, the plate may be withdrawn and another inserted without any change of position on the part of the patient. Before turning on the current, the operator should have informed himself of a number of details in regard to his apparatus. He should know just how much energy the particular tube he is using will stand, and for how long; and this once determined, he should use the same amount of current and the same rapidity of interruption with that tube for every case, or his results will not be uniform. He should also know by trial whether the vacuum of the tube is suitable for the case in hand. If it is already too low, the tube will not answer for that case; if too high, he must reduce it to the proper point, to be determined by the parallel spark-gap and the fluoroscope.

To know what degree of vacuum in a given tube is best suited for a radiograph of a given case requires, above all things, experience. But a general idea may be obtained by the appearance of the bones of the hand in the fluoroscope. If the shadow of the hand is so dark that the bones cannot be seen distinct from the flesh, the tube is only suitable for the thinner parts of the extremities, and for them only in case the tube in question permits the use of a large amount of energy. The relation between the penetration, as shown by examining the bones of the hand, and the power of the tube to produce a picture of a part of a given thickness is not absolute, but relative. For example, a high vacuum tube, giving a good fluoroscopic picture of the thorax, but which permits the use of a small amount of energy, may entirely fail to produce a satisfactory picture of even a part as thick as the adult knee-joint in any reasonable time; whereas a tube of very low vacuum indeed, through which a heavy current may be passed continuously for several minutes, will often produce a good negative in a much shorter time. A tube of medium vacuum, such that the bones of the hand when viewed through the fluoroscope show clear and distinct and sharply marked, while the flesh is much lighter, is, upon the average, best for general work.

A very high vacuum tube is but of little use for taking pictures. The operator will, in general, be obliged to establish his own standard, it being true of radiography as of most other practical arts, that an ounce of experience is worth several pounds of precept.

In general, one is much more likely to expose for too short a time rather than for too long, and whereas the negative produced by an over-exposure is still capable, with careful development, of furnishing a good picture, an under-exposed plate is hopeless, and no amount of development will bring out that which is not there.

Distortion.—Owing to the fact that the *x*-rays originate from a point or focus upon the surface of the anti-cathode, and proceed in straight lines in all directions from its surface, and since no one has as yet been able to refract the *x*-rays by means of prisms or lenses, it admits of a simple demonstration that the projections of any two points in the same vertical line placed between the surface of the anti-cathode and the photographic plate, but removed from the vertical dropped from the anti-cathode on the plate, will fall upon the plate at two points separated by a horizontal distance, the extent of which will depend upon the distance of the anti-cathode from the plate, the distance of the two points one from the other vertically, and upon certain other spacial relations unnecessary to elaborate.

In other words, a figure made up of many points, situated at various levels, will be projected upon the plate as a distorted image, and apparent deformities will be exhibited in the picture which do not exist. This distortion is more marked the nearer the tube is to the plate, the thicker the object, and the farther it lies from the vertical. In the case of the thinner parts of the body the distortion is slight at ordinary distances, but, in radiographs of the hip-joint, for instance, at similar distances it becomes extreme, and may render the negative quite worthless for diagnostic purposes. Distortion may be avoided by placing the tube as far away from the plate as is consistent with a reasonable time of exposure. To one acquainted with the relation of the tube to the plate in any given case and accustomed to inspection of *x*-ray pictures, moderate degrees of distortion may be

discounted, but inasmuch as the medico-legal relations of radiographs are important in certain cases, it behooves us to make a careful adjustment of the tube and the part, and to keep an accurate record of the data.

Attempts on my part to look at distorted pictures through lenses in order to correct the distortion have not as yet met with success.

Specific directions for the position to be assumed by a patient in order to get the part to be radiographed in the most favorable relation to the tube and plate might be given for different parts of the body, but the anatomical knowledge of the operator will usually suggest to him the best arrangement.

Some space, however, may be devoted to the use of the *x*-ray in the detection of renal and ureteral calculi.

The use of the *x*-rays for this purpose is of general interest, and most of my own work has been done in this direction. In my experience, the technique does not differ materially from that necessary to obtain good pictures of the bones, joints, etc.

The amount of electrical energy used must be considerable, in order to furnish enough penetrative power. The tube should be of a medium vacuum, and must permit the use of a heavy current for several minutes. In order to avoid the danger of burns, the tube must be placed at least twelve inches away from the skin, and the abdomen, thighs, and thorax should be thoroughly greased. The screen may also properly be used. The time necessary, with my apparatus, to produce a negative showing sufficient detail to make a positive or negative diagnosis varies from four minutes for a slender woman to ten minutes for a very stout man.

I am in the habit of placing the tube from fifteen to eighteen inches from the skin. The patient should lie upon his back, with the plate beneath him.

The knees should be flexed upon the thighs, and the thighs upon the pelvis, and supported in this position by a suitable cushion beneath the hams. By this means the back will be brought in contact with the plate.

The bowels should have been thoroughly evacuated, and the stomach should be as far as possible empty, at the time the picture is taken.

If the individual is small, or even of medium size, a plate fourteen inches wide will include the kidney region and the entire course of the ureter. For large individuals it is necessary to use a wider plate, or to take two pictures, one of the kidney region and one of the ureter.

If the first picture, including both kidney and ureter regions, is sufficiently good, it does not appear to me necessary to take another. A good picture should show the outlines of the vertebræ, their spinous and transverse processes, the structure of the sacrum in considerable detail, the outlines of the pelvic cavity, the last two ribs, the psoas muscles, and to establish a negative diagnosis, the lower half of the kidneys with fair distinctness. A much worse picture than this, however, will, in the majority of cases, furnish a positive diagnosis of kidney stone, and I have been able to see the shadow of a ureteral stone, weighing but two and one-half grains, on a plate which did not fulfill the above requirements.

An oxalate stone, as large as the last joint of one's little finger, casts a shadow fully as distinct as, for instance, the last rib.

But for diagnosis establishing the absence of stone one must, of course, obtain the very best possible negative. If the structures are seen, as above described, I do not believe that any calculus can fail to cast an appreciable shadow on the photographic plate. The plates should be dry before a definite opinion is given as to presence or absence of a stone, and should then be examined by standing them in front of a piece of ground glass, behind which is a source of light. If the plates are thin, it is advantageous to put two pieces of ground glass behind them.

The relative values of shadows upon such a plate can often best be appreciated at a distance of eight or ten feet; but, in my experience, the shadow produced by a stone, if it shows at all, is so distinct as to be absolutely unmistakable. Nor should an opinion be given unless such is the case.

There are several pit-falls into which the inexperienced and unwary may fall in regard to the diagnosis of kidney stones as shown by the *x*-rays. It is positively necessary that the negative should be good enough to show the previously enumerated normal structure. A plate which does not do this is worthless, usually, as a means of negative diagnosis. It is, moreover, necessary that the plate should be studied after it is dry in front of a suitable ground-glass screen.

A careless observer might mistake the tip of the transverse process of one of the lumbar vertebræ where it projects beyond the border of the psoas muscle for a stone. The tip of the twelfth rib in certain cases in which this rib is very short, and its proximal extremity not clearly defined, may lead to the same error.

Bacterial colonies are very frequent upon the gelatin films of certain *x*-ray plates, and at times might lead to error. But with a little practice they are not difficult to distinguish from the shadow of a stone. If the plate be looked at by reflected light from the sky, one can see that these spots produced by colonies of bacteria are not mere shadows, but represent a gross mechanical change in the gelatin film. In order to avoid their occurrence some manufacturers impregnate the emulsion with formaline.

There are, moreover, certain shadows which occur upon radiographs of the pelvis which might well be mistaken by the inexperienced for stone in the ureter. I have found these spots in three cases, and as yet I do not know their nature. They occur as rounded shadows varying in size from a B.B. shot to a small buckshot. Several are usually found upon one picture, and sometimes upon both sides of the pelvis. They are of about the same density as the ureteral stones. These shadows are arranged on a line which forms a gentle curve, with its convexity outward and downward, quite close to the bony contour of the pelvis, as projected upon the plate. They may be found anywhere from a point one inch above the spine of the ischium down to what seems to me to be close to the region of the prostate. They are, however, situated too far away from the median line either to be in the ureter or the seminal vesicle. I have thought that these shadows might represent calcareous deposits in the iliac veins.

Occasionally the crura of the diaphragm, as they pass to the body of the first lumbar vertebra, may cast shadows of a vague character which might possibly be mistaken for kidney stone. At least, such a statement is made by others, although I never had occasion to verify it.

There are also shadows resembling those cast by stones, the exact cause of which I have not been able to determine, and I have only noticed them upon the plates of one manufacturer. The plates manufactured by Cramer and by Seed do not

present these defects. The shadows are usually in the neighborhood of a minute spot no larger than the head of a pin where the film seems to be absent. The shadows themselves are somewhat larger.

Areas of fog may also produce deceptive appearances to the uninitiated, but a plate which is fogged at all is generally worthless for purposes of diagnosis.

Those plates which are sold for the purpose of taking *x*-ray pictures are often placed by the maker in paper envelopes ready for exposure. If the plates are entirely fresh when purchased and are used within a month this is a matter of no consequence, but if kept for some time the contact of the paper with the film produces a peculiar mottled appearance which renders the negative quite useless. It is better then to purchase plates which are not enclosed in envelopes and to put them in the envelopes shortly before they are to be used, or if plates already enclosed in envelopes are desired, to buy them a few at a time direct from the manufacturer and insist upon those recently made.

It is, of course, necessary to keep *x*-ray plates either in a thick metallic box or else in a room far removed from the coil; for the distance at which they may be affected by *x*-rays is very considerable.

The Development of X-ray Plates.—Any of the developers now popular are good enough, such as pyro, metol, hydrochinon, eichonogen, rodinal, etc.

It is very desirable that the surgeon should develop his own plates, if time can be spared for the purpose. It is too much to expect that any one else will exercise the same care and patience in the effort to perfect the work of another; and much valuable knowledge and satisfaction is to be derived from developing the plate which one has himself exposed. Moreover, the probable character of the negative is best known to the individual who made the exposure. He will, with a little practice, best know how to make the most of a given plate in order to show the thing which he desires to make prominent.

If there is reason to believe that a plate is overexposed, a diluted developer should be used; if not, it may be used of the ordinary strength.

When developing radiographs of the hip-joints and pelvis, I am in the habit of using a weak developer on account of the possible danger of ruining these negatives which cannot immediately be replaced without risk to the patient. To avoid danger of fogging an important plate, it is best to carry on the development in absolute darkness, only exposing the plate to the red light from time to time momentarily in order to judge how the development proceeds. For the development of hip-joint, spine, and pelvis cases, from ten to fifteen minutes is enough; for thinner parts of the body, from six to ten minutes, according to what is desired to show. If it is desired to show with the greatest clearness the structure of bone and to blot out the soft parts, a form of negative very popular for purposes of exhibition, the development should be carried to a point where the bones themselves appear distinctly dark and the soft parts can scarcely be distinguished from the uncovered portion of the plate.

If, on the other hand, the soft parts as well as the bones are to be preserved on the negative, and in all cases when the radiograph is to be viewed in the stereoscope, a more useful and interesting picture will be obtained by stopping the development while the soft parts are still quite a little lighter than their surroundings and the bones are gray but perfectly distinct.

In this description it is assumed that the exposure has been sufficiently long; otherwise, no amount of development will serve to bring out detail which is simply not there.

The use of the so-called "acid-hypo" bath which hardens the gelatin film and prevents the most annoying accident known as "frilling" is well worth the additional trouble involved in its preparation.

While those unaccustomed to the examination of *x*-ray negatives sometimes find it difficult to appreciate what they represent, and it is therefore necessary to prepare prints or positives, yet much of the value of the radiograph is thereby lost unless the printing is in painstaking and skilful hands. I have been unable to get professional photographers to do this work well, and therefore do it myself when I must, but the surgeon rarely has sufficient time to devote to this and must put it into the hands of another.

Satisfactory prints of plates showing kidney and ureteral stones are especially hard to make. The different portions of the body are inevitably penetrated to different degrees, and, in order that every portion of the plate should be printed to the proper density, it is necessary to use screens of tissue paper when printing by daylight.

The proper arrangement of these screens for a given case must be learned by experience.

Stereoscopic Radiography.—Although a good deal of attention has been given to this method of taking and looking at radiographs in England and Germany, and to some extent in Canada, so far as I am aware but little work of this kind has been done in the United States; and the main purpose of this paper is to call attention to certain advantages which may be obtained by this means with but little additional trouble and expense. The technique is quite simple, and demands but little more care and attention than the taking of two ordinary separate pictures. The advantages which may be claimed for stereoscopic radiography are that it renders the localization of foreign bodies simple and accurate; the character and extent of deformity in cases of fracture cannot be so well appreciated in any other way. The exact position of bones in cases of dislocation are shown in their true relations, and the same is true of deformity of bones produced by disease and congenital anomalies. The relations and origins of tumors growing from bone may be appreciated in parts of the body which are not open to ordinary palpation. For instance, tumors growing from the anterior wall of the sacrum at a high point, and certain diseases of bone, can be recognized at an early stage with great clearness, so that it may be said that by the use of the stereoscope the value of radiographs is notably increased.

The method depends for its value upon the well-known principle of the stereoscope, viz., that in order that we may see any near object, as a solid body showing relief, and appreciate the special relations of different points of the body to one or another, it is necessary to view it with both eyes. The effects produced by the stereoscope depend upon the production of two pictures taken from two different points of view, and the separation of the points one from the other is made equal to about the distance between the visual axes of the two eyes, viz., two and one-half inches.

In radiography, a little more or a little less does not appear to be of great consequence.

The method may be applied in two ways. Two pictures may be taken from the same point of view, the object being moved, or the object is kept sta-

tionary and the second picture is taken from a point distant two and one-half inches from the first. As applied to radiography, this principle may be utilized in several ways which vary only in detail. The *x*-ray tube is placed over the photographic plate with some part of the body intervening, and a picture is taken. The plate is then removed, and a second plate is substituted without moving the object. The tube is moved two and one-half inches horizontally, and a second picture is taken.

One-half of the plate may be screened by a sheet of lead during the first exposure, and in the second exposure the first half is screened and the second exposed. When this latter method is used, the plate is photographed, and thus reduced in size to a degree which renders it suitable for viewing with the refracting stereoscope. A print is made from the reduced plate, and looked at in the ordinary refracting stereoscope with which everyone is familiar.

There are optical difficulties in the way of the construction of the refracting stereoscope for looking at pictures of large size which appear to be insurmountable at the present moment; at least, my efforts in this direction have not met with success.

Another method which has chiefly been used in England is as follows: Two radiographs are taken from different points of view; prints are made from these plates, and viewed in the Wheatstone reflecting stereoscope. The pictures are, of course, life-size.

Both of these methods are subject to certain disadvantages. A good deal of time is required before the print can be prepared, and much care is necessary to mount them properly; considerable expense is also incurred. Moreover, when the pictures are diminished in size to the extent necessary for the use of the refracting stereoscope, the finer details are not so easy to see, and in general it may be said that prints made from radiographic plates are never as full of sharp detail and contrast as are the original negatives.

When the prints are to be viewed in the reflecting stereoscope, it is necessary that one of them should be printed reversed, or from the glass side of the negative.

The difficulties of producing a clear picture in this way are considerable.

They may be overcome by rendering the light rays which fall upon the plate parallel.

This can be accomplished by placing the printing frame at the bottom of a cylinder of approximately the same size as the frame and about six feet long.

In this way the clearness of outline in the print may be preserved, but the method is troublesome.

This difficulty may also be overcome by printing one of the pictures by the carbon process in which the sensitive film may be floated off and reversed and transferred to paper under water.

The mechanical details are troublesome, difficult, and expensive, and some distortion of the film is very likely to occur during the transference.

A third method, which I have been using with satisfaction, is to view the negatives themselves by transmitted light with the aid of a Wheatstone reflecting stereoscope.

The advantages of this way of looking at radiographs appear to me to be considerable.

1st. Time is saved. The negatives may be put in the stereoscope within one hour of the time when the exposures were made—obviously a great practical advantage.

2d. None of the fine details of the negative are lost, whereas in negatives made with a low vacuum tube it is often possible to make out stereoscopically the muscles, tendons, ligaments, subcutaneous fat, and other structures in a manner so vivid as to be quite startling. It is, in my experience, hopeless to attempt to reproduce these details with the same degree of clearness in a print. When stereoscopic pictures of the entire pelvis and both hip-joints of adult individuals are taken, as is often desirable, in order to contrast the two sides of the body, the method presents certain difficulties. The tube must be placed a long distance from the plate, in order to avoid undue distortion, and consequently much longer exposures are necessary, but for all ordinary pictures these difficulties do not obtain. The necessary apparatus for making and looking at stereoscopic pictures may easily be improvised at a cost of a very few dollars. For taking the pictures the tube-holder already described and the plate-holders answer well. To the tube itself is attached a paper protractor from the center of which hangs a weighted thread, so that the inclination of the plane of the anti-cathode to the photographic plate is indicated by the position of the thread, where it cuts the angles marked on the protractor.

The rotation of the tube upon a horizontal axis varies the angle to any desired extent. The thread also serves as a plumb line whereby the relation of the anti-cathode to the center of the plate is easily seen. The plate and the object to be radiographed are arranged beneath the tube in such a manner that the anti-cathode lies one and one-quarter inches to one side of the vertical dropped from the center of the anti-cathode to the middle of the plate, and the plane of the anti-cathode is inclined slightly toward the vertical.

Theoretically, the tube should be set at angles with the vertical, which vary for different distances at which the tube is placed from the plate, as follows:

At 35.7 inches the angle of the tube should be changed, after taking the first picture, to the extent of four degrees.

At 23.8 inches the angle should be six degrees.

At 17.8 inches the angle should be eight degrees.

At 13.2 inches the angle should be ten degrees.

These angles and distances include all probable limits at which *x*-ray pictures are likely to be taken. Practically, the exact angle is of no great moment. The apparatus having been properly adjusted, the exposure is made. The photographic plate is then withdrawn from the holder and removed to another room. Another plate is then inserted into the holder without moving the part which is to be pictured. The tube is then moved horizontally two and one-half inches, or one and one-quarter inches the other side of the vertical. The tube is then rotated through the proper angle, and another exposure is made.

The most important practical point in the method is to place the tube far enough away, so that the distortion of the picture will not be so great as to interfere with the stereoscopic union of the two images, which is necessary in order that the effect of binocular vision may be produced. It is of advantage to place the plates in the stereoscope, hereinafter to be described, at the same distance from the mirrors as they were from the tube when the pictures were taken. Experience shows that pictures may be taken without undue distortion, as follows: The hand at 13½ inches; the elbow, 16 inches; the foot and leg, 16 inches; the knee and shoulder, from 18 inches to 24 inches, according to the individual; the hip-joint, 24 inches; the pelvis as far away as is consistent with the penetrative

power of the tube; the head, 24 inches or more, the thorax at least 24 inches.

The plates exposed in this way constitute stereoscopic pictures. For viewing these pictures, I have found the following arrangement convenient: A hardwood plank five feet long, one and three-quarter inches thick, and eight inches wide, serves as a base for the stereoscope. In its center are arranged two plain plate-glass mirrors, each one foot square. These mirrors are set at an angle of ninety degrees to one another. The apex of the angle faces one of the long sides of the plank. The mirrors slide in grooves back and forth at right angles to the long axis of the plank. Upon either side of the mirrors there are two wooden frames for holding the negatives, and also a piece of ground glass. These frames are made to hold plates measuring eleven by fourteen inches, which size is sufficiently large for most purposes. Plates of any smaller size can be used, and those of eight by ten inches are often convenient. The frames are so arranged upon brass plates suitably grooved so that they slide easily along the plank; or upon a second brass plate superimposed upon the first at right angles thereto. And one of the frames may be raised or lowered by means of four large set screws with milled heads. Upon either end of the plank is placed a slate box containing two electric-light bulbs. These bulbs are set upon a block of wood perforated at the four corners by four thick vertical brass rods, which also serve to conduct the current which lights the bulbs. The bulbs may be raised or lowered by means of a brass rod which projects through the top of the box.

These electric bulbs serve to illuminate the negatives by transmitted light. Two sixteen candle-power lights are usually sufficient in either box, unless the negatives are very thick, in which case thirty-two candle-power lights may be substituted. In using the apparatus, one or two pieces of ground glass are placed in the grooved frames close to the front of either box, and the negatives are placed one on either side, facing each other in the grooves made for them next the mirrors. The observer sits down in front of the middle of the plank with one eye on either side of the angle made by the mirrors, from which the plates should be equidistant, and moves the mirrors toward him or away from him until the two images upon the negatives are superimposed, when the stereoscopic effect is appreciated.

As before stated, the effect occurs most easily when the plates are as far from the mirrors as they were from the tube at the time of taking the radiograph. It sometimes happens that certain individuals are at first unable to make the two images join and appear as one. But a very little practice usually a few moments, suffices to overcome the difficulty; and the habit once acquired, it is hard to see the pictures separately even when they are displaced considerably from their proper positions. It is desirable that a darkened room should be used to get the best effect. It is also desirable that the pieces of ground glass should be placed close to the box enclosing the lights, so that no light is observed except that which comes through the pictures. For this method of inspection the negatives should not be excessively dense, and surprisingly good effects are obtained with negatives so thin as to be disappointing when viewed by ordinary daylight.

It is by no means necessary to construct so elaborate an apparatus for viewing these pictures stereoscopically. The mirrors may be set in a simple box of wood and placed upon an ordinary table. Two other blocks of wood, suitably grooved for holding the plates and the ground glass, may be placed on either side of the mirrors, and any fairly powerful source of artificial light will answer for illumination. The pictures must, of course, be upon the level, or they will not combine. I have found this method of looking at x-ray plates very useful in a variety of conditions. The depth of foreign bodies from the surface and their relations to bones are appreciated with great ease. The character and degree of displacement in fractures can be recognized with great accuracy; the same is true of dislocations. The relations and depth of bony lesions from the surface can be accurately located. The exact character of a recent operation done upon a bone can be described as accurately as though the observer had seen the operation performed; and a much clearer idea of the structure and relations of bony tumors can be obtained than is possible by any other means that I am acquainted with, except an open operation.

The limits of this article do not permit me to treat of special lesions nor of special cases, and I have purposely confined myself to a general consideration of the topic.

It is my hope that I may at least have influenced others to try a method which but slightly increases the necessary trouble and expense of taking radiographs, and at the same time furnishes much greater clearness in the results obtained and enhances the value of radiography in several directions to a marked degree.

12 East Fifty-eighth Street.

CAN NASAL CATARRH AND CATARRHAL DEAFNESS BE CURED?

By CAROLUS M. COBB, M.D.,
BOSTON, MASS.

A question asked nearly every day of those engaged in treating the diseases of the nose and throat is whether nasal catarrh and catarrhal deafness are curable. The patient who asks the question generally has a pretty definite opinion on the subject and does not believe that they can be cured. This idea of the incurability of these diseases, which is so generally accepted by the laity, is the result of the personal experience either of the patient or of his friends, or of the offhand statement of the general practitioner, who is either too busy or has too little faith to try to do anything to relieve the condition. It must be confessed that most of the treatment used for these diseases in the past, and perhaps much that is used to-day, has been palliative rather than curative. It is a self-evident truth that however useful palliative treatment may be in acute disease it is not sufficient for the cure of chronic disease. If any proof were needed of the inefficiency of a large part of the treatment used in the catarrhal conditions of the nose, throat, and ears, it would only be necessary to call attention to the history of an ordinary case of chronic catarrhal inflammation of the middle ear, how in spite of the usual treatment one attack of acute inflammation follows another at varying intervals with partial recovery between the attacks, but with the hearing capacity reduced a little after each until the hearing is practically lost. That the disease may progress more slowly under treatment is undoubtedly true, but the treatment usually employed does not prevent the occurrence of the acute or sub-acute attacks of inflammation which are the cause of the progressive deafness in these cases. The treatment is rather directed to limiting the damage to the hearing which may result from each attack, and if we are so fortunate as to bring our patient through an acute attack without any noticeable im-

pairment of the hearing capacity, we feel that we have done well. This method of treatment has led in the last few years to the invention of a multiplicity of instruments to overcome the results of middle ear inflammation by mechanically moving the drum membrane and the ossicles. Whether these devices are useful we will not now consider, but certainly no one claims that the acute attacks of inflammation of the middle ear are in any way prevented by their use. It is a well recognized clinical fact too often lost sight of that acute and chronic catarrhal inflammation of the middle ear has its origin in the nasopharynx, and that the inflammation reaches the middle ear cavity either by the sudden blowing of some of the discharge which is present in the nasopharynx into the middle ear, or by, what is probably the more common way, the extension of the inflammation to the mucous membrane of the Eustachian tube and so to the middle ear. An exception to this method of extension exists in those cases of acute inflammation of the middle ear occurring in the course of some acute diseases of the respiratory tract, such as pneumonia, influenza, and some of the acute forms of coryza. In these cases the middle ear is involved coincident with the inflammation of the mucous membrane of the upper respiratory tract.

Permanent impairment of the hearing may result from the first attack of middle-ear inflammation, but progressive catarrhal deafness does not follow unless the inflammation of the upper respiratory tract also causes a chronic nasopharyngitis. If the assumption is correct that the nasopharynx is the source of the infection, and that the inflammation of the mucous membrane of the middle ear is a part of the general inflammatory condition of the nasopharynx, then it must be evident that to prevent the progress of the ear disease it is first of all necessary to cure the catarrhal inflammation of the nasopharynx. This at once brings up the question, Is a catarrhal disease of the nasopharynx curable, *i. e.* curable so that it will not return upon the slightest exposure or indiscretion? To answer this question it is necessary to have a clear understanding of the disease and the causes which may produce it. I have attempted to show, in an article in the *Archives of Otology*, Nos. 2 and 3, Vol. 29, that chronic catarrhal inflammation of the nasopharynx, with the exception of those cases which may be caused by a local syphilitic or tuberculous lesion, or by adenoids, is a secondary disease caused by a collection of fluid in some one or more of the nasal accessory sinuses, and that a chronic discharge in the nasopharynx differs in no way from a chronic discharge in other parts of the body, and that it should be treated in the same way, *i. e.* by improving the drainage of the cavity from which the discharge flows. This plan of treatment is followed by the general surgeon, who does not expect to cure a chronic discharge by washing the surface over which the discharge flows with antiseptic or astringent lotions; but this comprises the larger part of the usual treatment of nasal and nasopharyngeal catarrhs.

It is not so very long ago that the general surgeon did his work in the same way, with the same results that to-day follow the practice in the treatment of the diseases of the nose and throat. An illustration of the different explanations which are given for similar conditions, is furnished by an eczema of the skin around the ear, in connection with a purulent discharge. In this case it is at once assumed that the purulent discharge from the ear is the cause of the eczema, but we explain the presence of enlarged lymph follicles in the pharynx by the assumption that they are caused by indigestion, by uterine disease, by the hepatic diathesis, or by some other bizarre condition. As a matter of fact, there is no evidence that an enlargement of a lymph gland in the pharynx differs etiologically from an enlargement of lymph glands in other parts of the body, and as we consider such enlarged glands, in the axilla for instance, to be due to infection, we should so consider the enlarged lymph follicles of the throat. These glands, which play so important a part in chronic disease of the nose and throat, may be infected by the inspired air in mouth breathing, by foci of inflammation in the nose, throat, ear, and mouth, or as a part of a general systemic infection. It is not the purpose of this paper to discuss these enlarged follicles of the pharynx, only in so far as to show their relation to and dependence upon the general inflammatory condition of the upper respiratory tract. This infected tissue in or around the Eustachian tube, and possibly in the middle ear itself, is of the utmost importance in cases of chronic catarrhal deafness, and its removal by operation, even if it were possible to remove it completely, would be of temporary benefit only, if the source of the infection were not healed.

I do not wish to be understood as speaking against operations for the removal of hypertrophied lymph tissue from the pharynx and nasopharynx, because I realize fully the beneficial results which follow these operations, but I do wish to emphasize the fact that the treatment should not be considered complete until the source of infection which produced the enlarged glands is found and healed. I believe that it is possible to accomplish this result in practically all cases of post-nasal catarrh, and in this way cure the disease. If this result can be obtained, the progress of the deafness can be stopped, and the hearing will improve—in some cases a great deal and in others a very little, depending in a great measure upon how extensive the changes are which have taken place in the middle ear cavity. The improvement in the hearing is caused by the disappearance of the inflammatory thickening of the mucous membrane lining the middle-ear cavity or of that covering the bands of new tissue which may have been formed. It is quite probable that the immobilization of these bands of tissue by inflammatory thickening, has a direct and decidedly bad effect upon the hearing. If the bands of new tissue are so situated that the disappearance of the inflammatory thickening allows of greater freedom in the movements of the auditory mechanism, then the hearing will be improved, and if the inflammatory attacks can be prevented from recurring, it will remain improved. Now, as to the source of the discharge in post-nasal catarrh, we should bear in mind that it is caused in the same way as a chronic discharge in other parts of the body, *i. e.* that it is the overflow of an infected and inflamed cavity, the drainage of which is interfered with to such an extent that it does not heal, or that there may be diseased tissue within the cavity which prevents spontaneous healing. We should, therefore, examine each case in regard to the history, the course, and the present condition of the nose, throat, ears, and teeth. To me the history of these cases is very interesting, and I am surprised at the number which can be traced to the infectious diseases, and to the purulent rhinitis of children. While diseased teeth do not play the important part in the production of antral empyema, that they were formerly supposed to, still it is always well to bear them in mind as a possible etiological factor in the production of a post-nasal discharge. The two chief obstacles to the correct conception of nasal and post-nasal discharge, and therefore to their successful treatment, have been and are to-day, first, the importance which has been attached to obstructed nasal respiration, and secondly, the supposed rarity of empyema of the accessory sinuses. I am the last to deny the pernicious results which follow mouth-breathing, but *post-nasal catarrh*

is not caused in this way, and operations upon the nose to relieve nasal obstruction are only useful to relieve the condition of the oropharynx, the larynx and the bronchial mucous membrane, but they do not relieve post-nasal catarrh, only in so far as they incidentally, or accidentally, improve the drainage from the accessory sinuses. The relief following the removal of adenoid vegetations from the vault of the pharynx has been held as furnishing absolute proof of the relation of nasal obstruction to disease of the middle ear, but a larger experience and closer observation have shown that there is no constant relation between the degree of nasal obstruction caused by adenoids, and the amount of the ear disease, and that it is the location of the new tissue in or around the entrance of the Eustachian tube, and not the obstructed nasal respiration, which is the cause of the involvement of the middle ear. Another illustration of the harmlessness of nasal obstruction is furnished by those cases of deviated septum, in which the catarrhal disease of the nose and ear is upon the unobstructed side.

In regard to the rarity of disease of the sinuses, opinion has undergone a rapid change in the last few years, so that from being the rarest of recognized diseases fifteen years ago, it has come to be considered as one of the commonest that is found upon post-mortem examination; the percentage found by different men who have studied the question varies from twenty-nine to forty-three. In the living, Fein reports from Chiari's statistics of his private cases, two per cent. of diseased sinuses, and Lichwitz reports about the same percentage (1.98 per cent.). It will be at once seen that the larger part of these cases remain unrecognized during life. It certainly would not be unreasonable to assume that these unrecognized cases of nasal empyema are the cause of an incurable catarrhal disease. We certainly could not reasonably expect a discharge from a nasal empyema to cease under treatment, so long as the true condition was unrecognized, and I believe that the fact that over ninety per cent. of the disease of the nasal accessory sinuses is unrecognized during life, explains the failure to cure post-nasal catarrh and catarrhal deafness. The percentage of unrecognized cases is probably larger than the figures given, for the reason that the post-mortem records are taken from unselected cases, while Chiari's and Lichwitz's percentages are from cases which applied to them for treatment of the nose, throat, or ear.

It is evident that a post-nasal catarrh that is caused by, or is rather the overflow from an affected sinus, will not be readily cured by spraying or douching the nasal cavities, no matter how thoroughly and persistently it may be done. The use of sprays and douches does afford a certain amount of relief by the removal of the irritating discharge which accumulates in the nasal chambers. This discharge causes congestion and often excoriation of the nasal mucous membrane, and these conditions are increased if the collection is allowed to remain in situ long enough to decompose.

Any satisfactory treatment of the so-called catarrhal diseases of the nose and throat must be based upon a thorough knowledge of the anatomy and physiology of the nose and throat and of the sinuses which drain into them, upon a knowledge of the principles of general surgery, and lastly upon a painstaking study of each individual case. If we are content with the statement that the patient has catarrh, and wash out the nasal chambers and prescribe a spray or douche for home use, the diagnosis will be easy but the cure will be delayed. If we patiently search for the source of the discharge, it may be a question of weeks of painstaking attention before we can be absolutely certain of it, but when we have found it the prospect of a permanent cure of the disease is good.

In regard to the treatment of these cases, that will be determined by the amount and persistence of the secretion and by the trouble which it may cause, whether it is so slight that it is simply an annoyance to the patient, or so severe that it causes disturbance of the general health. It may be the cause of progressive deafness, of laryngitis, of asthma, or of bronchitis.

The amount of the discharge is not an index of the effect produced, as often the most disastrous results are caused by catarrhal disease which is accompanied by a very slight secretion, and on the other hand a profuse discharge may never be any thing but an annoyance to the patient or disgusting to his friends. We should therefore give due consideration to all of the phases of the disease in each case and be equally on our guard against doing too much in some cases and too little in others. I will give the history of a few cases and the plan of treatment followed in each case, simply to illustrate a few of the many complications of the so-called catarrhal disease of the nose and nasopharynx.

Case I.—Miss E. L., aged 23, had suffered for three years with intermittent attacks of Eustachian tube catarrh, which were sure to follow each acute coryza that she had. The Eustachian tube catarrh had always yielded readily to treatment, but she was completely discouraged because it kept recurring. She had such middle turbinals as I called attention to in the article on Nasal Empyema in the *Archives of Otology*, mentioned above, and no other obstruction to nasal respiration or drainage. I removed enough of the middle turbinals to give good drainage from the accessory sinuses. A month later she had another acute coryza, which was followed by a slight tubal catarrh and since then, for a period of three years, she has had no further trouble. I have followed this case very closely and with a great deal of interest, because it was one of the first upon which I operated with the purpose of improving the drainage from the accessory sinuses, in an ordinary case of post-nasal catarrh.

Case II.—M. L., aged 44, had suffered with secretory catarrh of the middle ear on both sides for two years. She had been under treatment, but as soon as the serum was removed from the middle ear cavity it would again accumulate. The posterior third of the nasal chambers and the nasopharynx were inflamed and of a deep red color. It seemed to me that there would be sufficient room for drainage from the sinuses, if the tissues could be freed from inflammation. I accordingly made applications of solutions of iodine and ichthyol to and around the middle turbinal and gave directions to have the nasal chambers thoroughly cleansed several times a day. After three weeks of this treatment the condition of the nose and throat was so much improved, that the fluid ceased to reaccumulate in the ears and the hearing was restored to practically normal. This improvement continued for one year, when following a coryza there was a slight return of the ear trouble. It yielded readily to treatment and there has been no return since, nearly two years.

Case III.—Mrs. F. O., aged 47, had been gradually growing deaf for five years. The history was typical of chronic catarrhal deafness, *i. e.* the hearing had been decidedly affected during or after each cold, but had improved after the subsidence of the coryza. She had gone on becoming deaf and partially recovering alternately, until she came to me with an attack which did not so readily improve, or rather the hearing had been permanently reduced

so much that she had become alarmed. She had hearing for the watch of 6-48 in one ear and 16-48 in the other. Treatment by politzerization and improving the drainage from the accessory sinuses by the removal of enough of the middle turbinals to give sufficient room between them and the outer nasal wall, was successful in arresting the disease, and the hearing gradually improved, until it was 16-48 in the poorer ear and 30-48 in the better. The hearing has remained stationary for eighteen months.

These cases are a fair illustration of what may be accomplished in chronic catarrhal deafness by attention to the condition of the nose and throat. I have not noticed any striking cures of that most troublesome of all symptoms, tinnitus aurium, and I am of the opinion that whatever effect the cure of the nasal or nasopharyngeal disease may have upon the tinnitus is produced very largely by the subsidence of the congestive or inflammatory thickening in the middle ear. The following cases illustrate other complications of nasal disease.

Case IV.—Mrs. M. E., aged thirty-two, consulted me in March, 1900. She had always enjoyed good health until she had scarlet fever, at the age of twenty-two. Since then she had suffered from frequent attacks of bronchitis, complicated by asthma. She had also had what was diagnosed as malaria by a very competent physician. The asthma and bronchitis had gradually grown worse, especially during the winter months, and at the time that I first saw her she had not been able to lie down at night for several months; the bronchitis was severe, and she had lost flesh, and was weak, tired, and generally miserable. She consulted me to learn if there was anything about her nose or throat that could act as a cause of the asthma. I found upon examination that she had a bullous middle turbinal on the right side, an abundant discharge from the nasopharynx, and a chronic pharyngitis. She was advised to have the middle turbinal removed, and as she had suffered so much she was willing to have anything done which offered any hope of relief. Enough of the bullous middle turbinal was therefore removed to allow the walls to collapse, and to give good drainage anteriorly. The patient was relieved at once of many of the distressing symptoms, especially the asthmatic attacks; the bronchitis improved slowly but steadily, and when she returned from the country in September, she was in better health than she had been before for years. In November she contracted a severe cold, which resulted in bronchitis and one rather sharp attack of asthma. The bronchitis yielded readily to treatment, and the patient has remained free from asthma and cough during the whole of the present winter. She has called at the office occasionally during the winter to tell me how well she was feeling, and that she could hardly believe even now that all her trouble came from the diseased condition in the nose.

Case V.—Mr. E. H., aged thirty-nine, consulted me in November, 1899, on account of a nasopharyngeal catarrh, which caused him to clear his throat every few minutes, and as it was necessary for him to use his voice a great part of the time, the constant hawking was a serious matter to him. On examination, the mucous membrane of the nasal chambers was found perfectly healthy; there were no spurs, deflections, or hypertrophies. The nasopharynx was also free from focal disease. The middle turbinals were small, situated far back in the nasal chambers, and closely applied to the external nasal wall. I removed the anterior end of both middle turbinals sufficiently to give a good space for drainage. The operation on the left side was a success, but on the right side I did not remove enough, and after it had healed, the patient was conscious that the discharge into the nasopharynx was entirely upon the right side. I therefore did another operation on the right side, which was completely successful. The patient reports that the nasopharyngeal discharge and the constant clearing of the throat entirely ceased after the second operation and have not since returned, now more than a year.

Case VI.—J. B., aged seventy, consulted me in June, 1900. He had been annoyed for a number of years with a catarrhal discharge from the nose and throat, and within the last two years he had suffered from several attacks of acute bronchitis. The attacks were becoming more frequent, and were a serious hindrance to him in a business way, as every few weeks he would be confined to his room with an acute attack, and while they did not last long, he was never sure when he might suffer from another. He had been under treatment at various times for the nasal catarrh, but with only temporary benefit. In this case it was possible to see some of the discharge making its way down between the middle turbinal and the outer nasal wall. The middle turbinals were situated far back in the nasal chambers, and the mucous membrane covering them was deeply congested and granular in places, as though the discharge had excoriated the surface. I removed enough of the middle turbinals to allow free drainage, and curetted the membrane around the hiatus semilunaris. I cautioned him not to expect immediate relief, as, in my opinion, it would take two or three months for the mucous membrane of the sinuses, even with perfect drainage, to return to a healthy condition. In spite of my caution, he became impatient, and wrote me from New York City after six weeks, saying that he did not think that I had removed enough from his nose, but a month later, he again wrote me that the catarrhal trouble had entirely disappeared. I am able to report, after six months, that the catarrhal discharge has not returned, and that he is free from the attacks of bronchitis.

Case VII.—Miss E. W., aged twenty-three, consulted me in November, 1899, on account of an odor in the nose of which she was conscious at times. She was quite sure that the odor was entirely confined to the right side of the nose. There was some discharge into the nasopharynx, but there were no crusts either there or in the nasal chambers. Owing to the intermittent character of the odor and the absence of crusts, I was convinced that the accessory sinuses were the seat of the disease. I accordingly removed the anterior end of the right middle turbinal to improve the drainage, so that the sinuses might be washed out if necessary. The odor was increased at first, but in the course of a few weeks it entirely disappeared without my having had to resort to washing out the cavities. After three months she came back to have the other side operated upon, saying that she was not conscious that there was any trouble on the left side until after the right side was well, and that she had experienced so much relief from the operation upon the right side that she was anxious to have the left made as well as the right. The same operation was done as upon the right side, and it followed the same course. She had been free from the odor and from the nasopharyngeal discharge for more than a year.

Case VIII.—Mr. A. T., aged thirty-nine, came to me in November, 1900, to have polyps removed from the right nasal chamber. The history

of this case is both interesting and instructive; it is as follows: Eleven years before, while fishing on the Grand Banks, he had an ulcerated tooth (first molar) in the right upper jaw. His face was badly swollen, and remained so until he reached land, where he could have the tooth extracted. The tooth and face were in this condition for four or five months. Soon after the face began to swell, he first noticed a discharge from the right side of the nose, and this discharge has continued ever since. In 1896, he went to St. John's General Hospital, and had polyps removed from the right nasal chamber. The return of the polyps caused him to come to me to have them removed. This was done, and I afterward removed with cutting forceps and curette a large mass of diseased tissue from the anterior ethmoid cells. He was much improved, but there was still a purulent discharge from the nose, and I advised him to have the antrum operated upon, as I did not think that a disease of such long standing and of evident dental origin would heal by simply improving the drainage through the hiatus semilunaris. He readily consented, and I opened the antrum through the canine fossa. The antrum was large and filled with foul-smelling pus. It was washed out, the diseased tissue being thoroughly curetted, and was then packed with gauze. The washing and packing were done daily for the next ten days. At the end of that time, the water, as it returned from the antrum, was clear, and from that time on the washing and packing were done only every second or third day. The antrum remains free from pus, and has been so for nearly two months; the discharge from the nose has nearly ceased, the patient feels better in every way, and there seems a good prospect of a permanent recovery.

Case IX.—Miss E. B., aged thirty, consulted me in June, 1900, on account of a persistent pharyngitis. She had suffered with her throat for three years, and had been under treatment for long periods of time without benefit. The pharynx, the nasopharynx, and the posterior third of the nasal chambers were congested, the mucous membrane was thickened, and the lymph follicles of the pharynx were enlarged. The patient was conscious of a slight sore throat most of the time, and every few weeks suffered from an acute attack which lasted a week or more. There was no ulceration and no focal disease around the throat. The case was one that ordinarily goes by the name of a catarrhal inflammation, but of peculiarly persistent form. I felt about this case as I do about others of the same class, that the trouble originated in the nose. In this case the middle turbinals were situated far back in the nasal chambers; they were swollen and closely applied to the outer nasal wall. I therefore improved the drainage from the sinuses by removing a part of the middle turbinals. Nothing more was done, and the patient was advised to discontinue all treatment, so that we might know whether what had been done was sufficient. This case seemed to be a fair test of what could be accomplished in this way, as she had not only been under treatment by competent men, but had also tried change of climate, without permanent benefit. I am happy to report that without any further treatment the throat gradually improved, and the patient has spent the present winter in Boston without any of her former trouble.

Case X.—Mrs. E. G. M., aged thirty-four, has consulted me at different times in the last four years for a nasopharyngitis which yielded to simple measures. I had never been able to discover anything wrong with the drainage or with the nasal breathing, and I had come to the conclusion that at last I had found a case of simple catarrhal inflammation, depending perhaps upon some state of the general health. In August, 1900, she came again with apparently the same condition for which I had treated her before. Again, I could find nothing to cause the catarrhal discharge. The nasal respiration was not interfered with; the drainage was apparently perfect; there were no points of focal disease visible upon the most searching examination, and I was again led to believe that the case was one of catarrhal discharge without local cause. I therefore treated the case by making applications to the nose and nasopharynx, and gave creolin ointment to be used in the nose at night, and Seiler's solution for use in the morning, and in addition her general health was carefully looked after. In spite of this treatment, the disease dragged; it was sometimes better, and then, without apparent reason, the discharge would increase; in this way the case continued for four months. The general health improved, but at the end of that time the catarrhal disease was not well. I had considered the advisability of trying to improve the drainage, on the chance that there was some obstruction that was not apparent upon examination. At this time the patient came to the office with an acute coryza on the right side, and as I am always suspicious that a one-sided coryza means sinus disease, I went over the case again. During the examination, she asked if I thought a tooth which she had could have anything to do with it. I at once investigated the teeth, and found that the first upper molar on the right side was a pivot tooth, and the patient informed me that the dentist had told her that in putting it in he had split the root. The tooth had given her more or less trouble since it had been in, and for the last few days had been quite troublesome. There was no swelling around the tooth, but high up in the canine fossa the mucous membrane was red and swollen, and there were several small ulcers. I advised her to have the root extracted without delay, which she did. A small collection of pus was found adherent to the end of the root, but I was not able to make out any opening into the antrum. After this the catarrhal discharge ceased without further treatment, and has not since returned.

I have not reported a large number of cases of any class, but have rather given examples of each. A summary of the cases of middle ear catarrh which are caused or made worse by nasopharyngitis was given in the article in the *Archives of Otology* referred to above. It will be evident from the history of the cases reported that each case must be carefully studied, and that even then it may be a question of weeks or even months before we can be certain of the cause of the discharge; but if we bear in mind that a chronic discharge into the throat is caused in the same way as a chronic discharge in other parts of the body, and study the case in this light, we shall be in a position to treat it intelligently. A careful study of a large number of cases treated in this way has eliminated the personal equation, and has only confirmed my previous impression that the so-called catarrhal disease of the upper respiratory tract, with all its attendant complications, is curable and that, while many of the cases will require much time and observation, the results obtained will amply repay one.

THE NEED OF BETTER PROVISION FOR THE PROPER CARE OF CASES OF DELIRIUM TREMENS AND CASES OF DOUBTFUL MENTAL DISEASE.*

BY HENRY C. BALDWIN, M.D.
BOSTON

THE question of the proper care of persons suffering from delirium tremens and of those under observation regarding their mental condition was discussed this past year in Boston in a conference of the various unpaid boards of trustees of the city institutions. In Boston, in those cases which come to the official notice of the authorities, the persons are kept in prison cells until they are seen by two regularly appointed medical examiners and found to be suffering from delirium tremens or doubtful mental disease, are then sent to a penal institution on an island in the harbor, and are cared for in the hospital connected with this institution. This arrangement is far from ideal. In the first place, it is manifestly illegal to send these persons to a penal institution without trial or commitment of some kind. Individuals suffering from delirium tremens are sick—through their own fault, it is true—but as sick people they are not criminals, and should have immediate and proper medical care as much as if they were suffering from disease of the stomach, or other organs. In the second place, it is not humane that these people who are sick should be kept in prison cells any longer than is absolutely necessary to determine their condition. Under the present conditions after their condition is determined, it is necessary to wait for transportation by boat to the penal institution, and this very delay has in some instances been fatal. Of course, in cases of doubtful mental disease, when the patients cannot be committed to an insane hospital, it is manifestly illegal to send them to a penal institution.

The proper care of these two classes of cases is a problem that confronts all cities of considerable size. Most of the cities have shirked the solution of the problem, or rather have utterly ignored it. But the fact remains that these people are sick people and should be properly cared for. They are not insane, and they are not criminals. The fact that they are an undesirable lot and that nobody wants them has no weight in the proper consideration of the question; for it is not wise or far-sighted for any community to ignore a crying need that exists.

It is the duty of the medical profession to consider these problems and to offer some solution which will work to the good of the sufferers and of the community, and there can be no doubt of the value of the united opinion of the medical profession in solving this problem. It is for the purpose of bringing the matter again to the attention of medical men qualified to express an opinion on the matter, and for the sake of a full discussion of the question, that this paper is brought before you to-day.

Nothing exemplifies better the vast strides made in methods of caring for the dependent classes than the treatment accorded the insane less than seventy years ago and to-day. Previous to the establishment of the first hospitals for the insane, the insane were confined in penal institutions, and fared worse than criminals. In 1830 a hospital for the insane was built in Boston. It was placed between the Work House and the House of Correction, and when completed the insane were taken from those penal institutions, where many of them had been kept in strong wooden cages on wheels. In fine weather, as an extraordinary touch of kind treatment, these cages were drawn out of doors. When the hospital was ready it was a simple matter to wheel the insane in their cages to the new building. Here the intelligent and humane superintendent, Dr. John S. Butler, at once released them and treated them as human beings. To-day the process of evolution has brought a complete change in the knowledge and treatment of insanity. In the light of our present advancement in knowledge, it would appear that these cases of delirium tremens and of doubtful mental disease receive relatively as scant attention, and are as much neglected as were the insane seventy years ago.

In order to learn what custom is followed in the care of these cases in the cities of the United States, letters were sent to the authorities in twenty-eight principal cities, asking the following questions:

"1. What disposition is made of the cases of delirium tremens and cases of doubtful mental disease that are brought to your official notice? I wish to know whether these cases are sent to a general hospital, to an insane asylum, to the almshouse, jail, or kept in the cells in the police station,

"2. Can you tell me approximately the number of cases brought to your official notice each year?

"3. What medical attention do these cases receive at first; that is, in connection with the city prison, or whatever place these cases are taken to? Is there constant medical attendance, as there is in San Francisco, for instance; or do you depend upon police surgeons, or are there regularly appointed medical examiners who are called in to determine the condition of the case?"

Answers were received from over twenty cities. These replies show that various methods prevail in the different cities. It is well known that in New York, Philadelphia, and Chicago there are wards for the care of alcoholic patients and cases of doubtful mental disease in connection with city hospitals. In Washington, cases of drunkenness, if semi-concious or unsconscious, as well as cases of delirium tremens, are sent to a hospital at once. This method of caring for cases of delirium tremens is followed in New Orleans, Kansas City, Indianapolis, St. Paul, Cincinnati, San Francisco, Los Angeles, and Buffalo. In one city the majority of persons arrested suffering from delirium tremens are taken before the Probate Court and committed to the State Insane Hospital. Some of the cities take care of these cases in the jails; and some seem to combine all three methods, sending some cases to the insane asylum, some to the hospital, and some to the jail.

In Massachusetts the present method of caring for these cases is unsatisfactory. Letters sent to the principal cities of the State have elicited the following information: In two cities cases are cared for in the hospital connected with the city almshouse. There were less than a hundred cases per year in these two cities. One city commits its cases, less than half a dozen per year, to an insane hospital. In sixteen cities these cases, over four hundred in number per year, are cared for in the prison cells of the station house or in the jails.

It is impossible to get any statement of the number of cases of delirium tremens and of doubtful mental disease that come to the official notice each year in most cities. In Boston there have been about two hundred cases annually, for the last two years, that have been sent to the observation hospital connected with the penal institutions.

No doubt, with the present facilities and the existing methods of caring for these two classes of dependents in the different cities, they are as

* Read at the meeting of the American Medico-Psychological Society in Milwaukee, June 12, 1901.

well cared for as is possible. No intentional cruelty is practiced or would be tolerated. But the system, or, rather, the lack of system, is all wrong, and ignorance of the law excuses no man—or city.

In the first place, as has been before stated, people suffering from delirium tremens are sick people and need immediate medical care and proper nursing. It is difficult to see why a man who breaks his leg while drunk, or a patient delirious from fever, should be considered a proper person for a city hospital, while one delirious from drink, but dangerously sick, should be sent to jail or kept in a prison cell with less careful attendance.

Secondly, the custom that exists in some cities of committing a person suffering from delirium tremens to an insane hospital, though possibly technically within the letter of the law, cannot be commended. Such commitments put work upon the insane hospitals for which they were not intended, and to-day our insane hospitals are already overcrowded with legitimate cases, and should not be embarrassed by having cases sent to them that do not properly belong there. Such a custom would give a better percentage of recoveries for the hospital.

Thirdly, if the jails and prison cells are not the proper places to take care of such cases, and if insane hospitals ought not to be imposed upon, much more does it seem unsuitable that the decision as to the care of those persons should be left in the first instance to the judgment of some police officer. In Boston, for instance, these persons may have to stay over night and sometimes over Sunday in the house of detention or the city prison. If they are very sick, a physician is sent for; otherwise, they remain without medical care until the daily visit is made by the examining physicians. It is too much to expect a police officer to be a medical expert, and the numerous deaths that occur among these dependent classes in police cells should not be laid to the door of the police authorities, but the city should be blamed for permitting such an inadequate system for the care of these cases.

The time has come when the question of the proper disposition of these cases can no longer be evaded. Cases of delirium tremens and doubtful mental disease are irresponsible to a great degree, and the law makes no provision for them. A special reception hospital has been advocated. Such an institution under proper management and with constant medical supervision would be an ideal arrangement. Necessarily the establishment of this hospital would mean the expenditure of a large sum of money in the first instance, and a yearly appropriation for its maintenance afterward. For these reasons the immediate establishment of such hospitals would perhaps be considered Utopian in most cities.

But in all cities it would be possible to have a ward or pavilion in connection with the city hospital set apart for these cases. The city hospitals are instituted by the people for the care of the sick, whether deserving or undeserving, and are supported by the public moneys.

Attention should be called to the fact that cases of delirium tremens and of doubtful mental disease which come to the official notice of the city authorities are a limited class, so that were this small number added to the number of disturbed cases that always exist in any general hospital, the additional burthen would not be grievous. Against the objection that has been urged that such cases require specially constructed buildings and apparatus, specially skilled physicians and attendants, it may be said that many such cases are now well taken care of in general hospitals and private houses without these so-called essentials. It can hardly be believed that these desiderata are to be found in prison cells or penal institutions. At the present time most hospitals have a neurological staff, and it would be an advantage to house officers, nurses, and students to have larger opportunities to observe mental sickness. Many hospitals object to the admission of these cases because they fear that their admission may be the entering wedge which will open the door of the hospital indiscriminately to all cases of alcoholism and insanity.

It is undeniable that the cases that should be under medical observation in large cities much exceed those which are under discussion. In Bellevue, for instance, 5,205 patients were admitted to the alcoholic wards in 1900, and 2,425 to the insane pavilion.

According to the statement of the superintendent of the hospital, patients remain in the insane pavilion for about five days, or until it is determined whether or not they are insane. They are then discharged or transferred to other institutions. Alcoholic patients remain about three days. They are then discharged, or, if suffering from other ailments, transferred to the medical or surgical wards of the hospital. Patients suffering from the effects of morphine, epileptics, and hysterical patients are put in the alcoholic wards.

Aside from the humane standpoint, and on purely economic grounds, the establishment of separate hospitals or of special wards in connection with general hospitals for observation cases would, in most instances, cost less than the present system. Were such a place provided, many persons who are allowed at large because the police know of no place to which they can be sent would come under early observation, and their condition would be determined in time to prevent crime. According to the Attorney-General, the cost of one murder trial in Massachusetts may reach $15,000.

The first movement tending to proper care of these unfortunate people must be made by medical men. Without earnest and continuous effort upon our part, there is but little hope of improved conditions.

A NEW CONTINUED FEVER.

By EDGAR J SPRATLING, B Sc., M D.,
FORSYTH, GA.

We had here in the spring and early summer what is to me a new fever. The trouble began with malaise for three or four days, then muscular pains, especially of the neck; there were slight chilly sensations; the temperature rose to from 100° to 102°, the pulse was 110 to 120, the respirations 30 to 40; there was nausea, the patient had a hacking cough and mental depression, sometimes amounting to melancholia. The following day the pains were more pronounced, especially in the long bones and joints; headache was severe and accompanied with photophobia and dizziness on rising; the temperature was 104° to 106°, pulse 120 to 140, respirations 40 to 60 and shallow; the abdomen was sore and tympanitic; there was gastralgia, with disgust for food; the urine was scanty, offensive, and highly colored. The mind was periodically clouded, often actively delirious, according to the temperature, which changed rapidly, sometimes four or five marked fluctuations in the twenty-four hours; the slightest noise, disturbance, or exertion, mental or physical, caused rapid exacerbations. This was one of the characteristics of the disease.

Thus far this fever closely resembled dengue, and might in a few cases be confounded with grip. But in dengue the cases of a given epidemic will be much

alike as to violence; in this the widest possible range was found. In several cases the temperature reached 106.5°, in many not 100°. In dengue the surroundings have but little influence; in this they were nearly all-powerful. In dengue whole families are usually affected; in this rarely more than one member. The temperature of this fever was very susceptible to the action of antipyretics.

The symptoms given above lasted from two to five days, then gave way rapidly, all discomfort disappearing; the appetite returned, the pulse fell to from 85 to 100, the respirations to 30 or 40, and the patients expressed themselves as "feeling fine; could get up if only stronger." *But the erratic fever and scant urine persisted for from three to ten days longer*, and there were frequent profuse sweats. Then the fever ceased and the kidneys acted normally; the mind became clear, but mental and physical lassitude persisted in some cases for weeks.

Thus we see we have a close congener of, if not actually, Malta or Mediterranean fever.

Out of about sixty cases we found nearly one-half slight, confining the patient to bed only two or three days—the longest period was twenty-three days. The complications, in order of frequency, were bronchitis, enteritis, laryngitis, pneumonia, pleurisy, arthritis, and lymphangitis.

The prognosis was good when no organic heart lesion existed, when the strength was preserved, quiet was maintained, the kidneys were stimulated with alkaline diuretics, and depressant medication was avoided.

This is a high, dry locality, and neither malaria nor typhoid fever exists here; nor did any tests for either of these diseases give positive results in this fever.

Tonsillotomy Rash.—Wyatt Wingrave makes a report based on twenty-six cases. Of this number, three which were in-patients, proved to be scarlet fever, while in one diphtheria developed. The remainder were simple non-specific cases. The eruption generally appears on the second or third day, and is either papular, roseolar, or erythematous in type. It most frequently attacks the neck, chest, and abdomen, sometimes extending to the face and extremities. The earliest appearance noted is on the day following operation; the latest one is on the sixth day. Its duration is generally two or three days, but may extend to five days. After reaching its maximum intensity, it rapidly disappears without desquamation, but is sometimes associated with intense itching. It may occur at any age—the youngest patient was fourteen months and the oldest twenty-three years. With regard to sex, excluding the specific cases, sixteen were in females and six males. As a rule there is but slight constitutional disturbance, and the child does not appear to be any the worse. In those cases investigated the temperature was increased 1° to 2° F. Examination of the blood during the week following a tonsillotomy showed an increase in the number of the uninuclear white corpuscles. This leucocytosis rarely lasts beyond the tenth day, and is hardly surprising after the removal of so much lymphoid structure. The rash may be one of drug intolerance, since most of the patients cases were taking sodium salicylate and potassium bromide.—*Laryngoscope.*

Subnitrate of Bismuth as a Remedy in Obstruction of the Bowel.—H M Shallenberger states that in his experience, embracing a large number of cases at ages ranging from four to sixty-five years, extending over a period of more than fifteen years, the obstructed bowel has, in every instance, been relieved within forty-eight hours following an initial dose of bismuth. He notes several cases in which cathartics or enemata had been used either singly or conjointly, this treatment, in some instances, extending over nearly a week, but within two days following the administration of the bismuth, there was a movement or disintegration of the fecal mass. In all conditions of impaction, the muscle fibres about the obstruction undergo a contraction or spasm. The effect of the bismuth is sedative on the terminal nerves. The writer believes that the bismuth allays the irritation of the bowel, relaxes the spasm, and thus removes resistance to the passage of the obstructed feces. He orders in his cases the continued use of a saline water, and from the first at least thirty grains of sub-nitrate of bismuth at short intervals and continuously until there is an impression made on the fecal tumor.—*Therapeutic Monthly.*

A Peculiar Nervous Disease Occurring in Childhood with Motor Disturbances and Mental Weakness.—Bechterew mentions two singular cases described by O. Giese, and adds a similar one of his own. The first two patients were a brother and sister of twenty-five and thirty-two years respectively, who, after a mentally backward childhood, at puberty developed motor disturbances, taking the form of slow monotonous speech, intention tremor of the hands, twitching of the face, and unsteady gait. The reflexes were exaggerated, and the disease ran a slowly progressive course. The author's patient was a girl of nineteen, whose case differed from those described mainly in that the reflexes and muscular excitability were not increased, that the hands were poorly developed, that there were no local palsies, and that there were congestive manifestations in the extremities. The mental deficiency, tremor, and cerebellar ataxia led the author to locate the lesion in the cortex and in the cerebellum, together with a probable degeneration of the pyramidal and descending cerebellar tracts.—*Centralblatt fur Nervenheilkunde und Psychiatrie.*

A Study of the Temperature, Pulse, and Respiration in the Diagnosis and Prognosis of Certain Diseases of the Brain.—J. T. Eskridge says that a change in the character of the respiration, rather than in its frequency, is sometimes one of the first positive symptoms of organic intracranial disease, especially of tuberculous meningitis. A respiration more frequent during sleep or unconsciousness than during waking moments is strong evidence of organic disease of the brain. Apoplexy due to hemorrhage is attended with greater disturbance of the temperature of the body, soon after the occurrence of the stroke, than when due to thrombus or embolus. If the temperature on the paralyzed side remains higher than on the opposite side several weeks after the occurrence of the apoplexy from any cause, it indicates that softening or inflammation of the brain is going on, and lends great gravity to the prognosis. The author makes some tentative statements in regard to traumatism of the brain in its effects upon pulse, respiration, and temperature.—*Denver Medical Times.*

Obstetrical Rules.—When abortion is inevitable, plug the vagina with strips of gauze or some clean, soft material, and wait six or eight hours. The ovum will often be found in the vagina on removing the gauze; if not, plug again and wait. If any part of the ovum or decidua remains in the uterus, clean it out at once with the finger or curette, not hesitating to give an anæsthetic if any difficulty is met with. If there is a rise in pulse-rate and temperature, and the vaginal secretion is foul, give an anæsthetic, dilate the cervix, empty the uterus, and scrape it clean, no matter what stage the process of abortion has reached. In other words, use artificial dilatation, followed by emptying and cleaning out the uterus in threatened incomplete and complete abortion alike, whenever the uterine cavity becomes the source of septic intoxication.—*Indian Lancet.*

No Leprosy in the Faroe Islands.—A writer in the *Polyclinic* says that there is no leprosy in these islands, and that there is no history of there ever having been a leper-home there. Since leprosy prevails so extensively in the neighboring countries of Iceland and Norway, it becomes of much interest to ascertain what conditions have conduced to its extinction in the Faroes. In the Orkneys and Shetlands, where leprosy was formerly prevalent, it has become extinct within recent times.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 Fifth Avenue.

New York, September 7, 1901.

THE GROWTH OF THE DRUG HABIT.

WHEN intemperance is so universally associated with the abuse of alcohol it is time for the public to know that there are other and important considerations to be taken into account in direct connection with the growing vice. Dr. A. P. Grinnell of Burlington, Vermont, in the current number of the *Medico-Legal Journal*, has taken a so much broader view of the general subject that his treatment of the pernicious use of drug stimulants merits very serious study.

In his own State he has taken the pains to collect statistics from medicine vendors bearing on the increased use of the common narcotics as an evidence that stimulants, as such, have certain complementary relations to each other in meeting the natural cravings of human appetite. "If you should ask any one of your neighbors," says he, "'What stimulant do you take?' and that person was the advocate of what is called prohibition in Vermont, which means the prohibition of alcohol (the least of all in importance), he would probably say, 'Nothing.' But analyze his or her daily life; consider tea, coffee, tobacco, opium, cocaine, quinine, or any of the various table condiments like tabasco sauce, or some of the special brands of catsup, the patent medicines called tonics and blood purifiers, and you will find that there is not one who can say that he does not take some one of the list, and would miss it if he did not. To some men alcoholic stimulant is everything they seem to need to satisfy their craving. What is a stimulant to one, however, may not be to another, consequently there is a great variation in the character and amount of the stimulants used."

After seriously reflecting upon the matter, after watching the effect of the prohibitory law (so called), in Vermont, and having a well-grounded conviction that everybody indulged in the use of some artificial stimulant, he was led to make further investigation. Assuming that the law prohibiting the use of alcohol, except for medicinal or mechanical purposes, was enforced, then it appeared to him reasonable that many persons might be driven to the selection of some other stimulant as a substitute for alcohol.

His convictions regarding this point were well founded, as shown by a large correspondence with wholesale and retail drug vendors in Vermont, as well as with the proprietors of general stores in which medicines are sold as ordinary merchandise. In 130 of the regular pharmacies and in 160 of the general stores in the State of Vermont there were sold to regular customers every month 3,300,000 doses of opium, besides what were dispensed in patent medicines, and what the physicians prescribed, giving one and a half doses of opium to every man and woman in the commonwealth every day in the year! The inquiry was restricted to the commoner narcotics—opium, morphine, Dover's powder, paregoric, laudanum, cocaine, chloral, and cannabis indica. The amounts given in these instances were so large that Dr. Grinnell was at first led to believe that the vendors estimated by the year instead of by the month.

In some of the larger towns the monthly sales of opium ranged from three to five pounds, those of morphine from one to three pounds, paregoric and laudanum from one to six gallons, cocaine from one to four ounces, chloral from one to thirteen pounds, and Indian hemp from one to thirteen ounces! All this in a State with but 320,000 population!

The author, believing that to many quinine "is a great stimulant," has collected statistics regarding the relative increase of consumption of that drug. "A two-grain quinine pill," says he, "will flush the face as much as a drink of whiskey, unless one is accustomed to its use." Whether or not the conclusion is correct, there is certainly an immense amount of the drug used, averaging in different localities of self-prescribers from five to eight thousand grains daily. It is estimated that the aggregate quantity used in general sales would allow two grains daily to each man and woman in Vermont!

Comparing drug statistics with those of alcoholic stimulants "for medicinal, mechanical, or chemical purposes," there was enough sold in seventy-one towns to give an equivalent of $1.38 worth of liquor for every person. "All in all, over one-quarter of a million dollars' worth of liquor was legally required by a population of 182,356 people for medicinal purposes, and the health reports show no epidemic or undue prevalence of disease!"

Dr. Grinnell may well be surprised at the results of his interesting investigations, and he is well warranted in saying: "Sooner or later the reformers of the world have got to divert some of their feverish antipathy to alcoholic stimulants and consider calmly and intelligently the drug evil. The deleterious influence on the individual of all forms of drug addiction, and the consequent effect on society and all relations of mankind, make its consideration in its sociological and criminal aspects of paramount importance. The courts have never given much judicial importance to drug habits, but widespread development of drug addiction must surely, sooner or later, bring the matter into greater legal prominence."

The question of remedy, however, is unfortunately not an easy one for a thoroughly practical answer, for natural appetites cannot be controlled by legislative enactment, and thus far, all laws to such ends have been evaded. Those who attempt to compromise the situation strive to lessen the opportunities for temptation, and reasonable restrictions are the only ones that hold as deterrent elements. It is so with the restraint of prostitution, and with all typical "Maine" laws, and it will be equally so with the repression of the drug habit. Each man feels, in a certain sense, that he is at liberty to do as he pleases with himself. Hence there is good reason to acknowledge that "no law has yet been enacted which meets the requirements or is satisfactory to the

victim of the drug habit, to the reformer, or to the reformed."

For the physician who views the present situation of attempted legislative control, it may not be irrelevant to consider his own responsibility in the matter of abuse of alcohol and powerful drugs. It may not sound well to say it, but it is true enough that much of this trouble is due to him by the thoughtless manner in which he has popularized the use of these poisons. The retailers of these drugs merely find it profitable, in a business sense, to meet the demand. Reasonable restrictions of sale may do much to mitigate present evils, but behind all is the proper education of the public concerning the real dangers of these pernicious habits. In such laudable missionary work the medical man can take a becoming part, and thus possibly atone for much of that mischief which is now so far beyond the reach of immediate reform.

THE WITHDRAWAL OF CHLORIDES IN THE TREATMENT OF EPILEPSY.

EPILEPSY constitutes one of the most difficult and obscure problems in the domain of medicine, from the point of view of pathology, as well as that of treatment. So far as present knowledge goes, the disease must be looked upon as one in which the motor cells of the cerebral cortex undergo perturbation with undue readiness, as a result of the action of a great diversity of irritants. Intelligent treatment, therefore, must be directed to the removal of exciting factors so far as known, or to the prevention of their access, the suppression of the cellular perturbation if developed, and the correction of the cellular hyperexcitability. For the latter two objects sedatives are clearly indicated, and have been largely used, and of these the bromides in varying combination have proved most serviceable in a large number of cases. The first object has been most successfully attained through dietetic measures. The results of treatment, however, even under the most favorable circumstances, leave much to be desired.

A couple of years ago two French observers, Toulouse and Richet, upon the assumption that the body is more susceptible to the action of bromides if sodium chloride be withheld, as the former displace the latter from its combinations, recommended a dietary from which common salt was excluded and which they employed in twenty cases of inveterate epilepsy with admirable results. They administered daily, in conjunction with from 15 to 30 grains of bromides, 1,000 grams of milk, 300 grams of meat, 300 grams of potato, 200 grams of flour, 2 eggs, 50 grams of sugar, 10 grams of coffee, and 40 grams of butter. Encouraged by the recorded results, Dr. R. Balint (*Berliner klinische Wochenschrift*, 1901, No. 23) instituted similar treatment in 28 cases of epilepsy, 9 of more recent and 19 of longer standing. Inasmuch as the total withdrawal of salt was attended with distress, and as it was realized that the articles themselves entering into the dietary contained salt, the dietary was, after some preliminary observations, modified so as to consist of from 1 to 1½ liters of milk, from 40 to 50 grams of butter, 3 eggs, and from 300 to 400 grams of bread in which sodium bromide was substituted for common salt.

During the first few days of treatment there was in some cases no change and in others an apparent aggravation, while in still others improvement began at once. In the course of a week, however, improvement was the rule, with reference either to the frequency or the severity of the attacks, or both, and this continued throughout the entire period of treatment, and in some degree also subsequently thereto. Improvement in the mental state likewise was noted, while the bodily weight increased and the complexion became brighter. Ill effects from the bromides were not observed, the drug being required in less than the usual doses, and appetite and digestion not being interfered with. The treatment, it is thought, is best applicable in an institution. That the beneficial effects are not due merely to the character of the diet was shown by the omission of the bromide on the one hand and by the administration of sodium chloride on the other hand, and in consequence of which the attacks occurred with their previous frequency and severity.

PYRIDIN IN TOBACCO SMOKE AND THE CIGARETTE QUESTION.

AN editorial annotation which appeared in the London *Lancet*, some time ago, has attracted a great deal of attention in some of the lay journals of this country, principally for the reason that it runs counter to the commonly accepted beliefs with regard to the particular product contained in tobacco and its smoke which exerts the most deleterious effect upon the smoker. The article in question first points out that modern researches are distinctly tending to show that the poisonous effect of unlimited tobacco smoking is not due to nicotine. Of course, tobacco contains nicotine, but it is practically certain that nicotine does not occur as such, at any rate to any extent, in the smoke. By far the greater portion of the nicotine—the amount of which, in the Virginia tobacco used for cigarettes, has been shown not often to exceed one per cent.—is destroyed by combustion.

The agency by which the well-known symptoms following excessive smoking are produced is said to be the tar-oils formed in tobacco smoking, the chief constituent of which is pyridin. Nessler observed some time ago that the effects of tobacco are not due to nicotine, but to a volatile oil. His assertion has been confirmed by several other observers. The degree of toxicity of the smoke, however, probably depends largely upon the completeness of the combustion.

After having attempted the demolition of the old belief as to nicotine being the cause of the unpleasant symptoms subsequent to excessive smoking, the writer in *The Lancet* proceeds to discuss the comparative pernicious action of tobacco, as used in cigar, pipe, and cigarette, and reaches the conclusion that the cigar is the most harmful form of enjoying the soothing weed, followed in the order of injuriousness by the pipe and cigarette.

Some two years ago, *The Lancet* took up the cudgels on behalf of the much-maligned cigarette, and proved by careful analyses, undertaken at its own laboratory, that both the tobacco of which the best-known brands of American cigarettes were composed, and the paper in which they were wrapped, were pure. The MEDICAL RECORD, at about the same time, declared editorially that there was no valid reason for asserting that cigarette smoking was especially injurious *per se*, but that when practised by the young, or when inha-

lation was indulged in to any extent, the habit was undoubtedly harmful to health.

Used moderately, says Clifford Allbutt, tobacco is not injurious to most persons, and may have its indirect effects in soothing fatigue and restlessness. It is, however, as true of tobacco as of other agents affecting the nervous system, that the personal equation is to be regarded. The quantity consumed with impunity by one man is poisonous to another; each smoker must estimate his own resistance and regulate his doses accordingly. These wisely temperate comments apply to all forms of tobacco smoking. *The Lancet* puts its argument in favor of the innocuousness of the cigarette thus, "The combustion of the cigarette is probably more complete than that of the tobacco in a pipe, or of the uncut leaf of a cigar. But the pipe serves as a condenser, the condensed products not reaching the mouth. A good deal of condensation must take place in the cigar, and, moreover, the products reach the mouth and are absorbed." The position taken as to both points seems to be sufficiently comprehensible. But the argument in favor of the cigarette holds good only when the paper cigar is smoked in moderation, and the smoke from it is not inhaled. It is in the temptation to excess and to inhalation of the mild smoke that the peril of cigarette smoking lies.

Probably this view of the injurious influence of pyridin will not commend itself to all who have made a study of tobacco smoking, but at any rate there can be no doubt that the general public have very exaggerated notions as to the evil wrought by nicotine. Dr. Heinrich Stern attributes to carbon monoxide, which is a constituent of tobacco smoke, many of its poisonous qualities.

News of the Week.

The Tri-State Medical Society of Alabama, Georgia, and Tennessee.—The thirteenth annual meeting of this society will be held at the Tulane, Nashville, Tenn., on Tuesday, Wednesday, and Thursday, October 8, 9, and 10, under the presidency of Dr. M. C. McGannon of Nashville. The secretary is Dr. Frank Trester Smith of Chattanooga.

A New Hot Spring has been discovered at Mackinack Island, Mich. The spring is close by the city water works. The temperature of the water is 104°, but what its composition may be has not been ascertained.

Malaria a Notifiable Disease.—The New York City Board of Health has adopted resolutions to the effect that the officers of "public institutions, hospitals, homes, asylums, etc., be required to report all cases of malarial fever which come under their observation, giving the name, age, sex, occupation, and present address of the patient, and also information as to whether the attack is a primary infection or a relapse, and the address where the disease was probably contracted." Also "that all physicians in the City of New York be requested to furnish similar information in regard to patients suffering from malarial fever under their care." Circulars of information regarding the causation and prevention of malaria were recently issued and the board will send these in each instance to the residents of the places where the malarial infection has apparently been contracted. Postal-card blanks for furnishing the required data will be prepared and forwarded to institutions and physicians to facilitate the reporting of cases of malarial fever which come under their observation, as is done in the case of other infectious diseases.

The Mississippi Valley Medical Association, as previously announced, will hold its annual meeting next week, September 12–14, at the Hotel Victory, Put-in-Bay, Ohio, under the presidency of Dr. A. H. Cordier of Kansas City. An interesting program has been published and the meeting gives every promise of being one of the most successful in the history of the society.

Pessimism in Climatotheraphy.—At a meeting of the weather forecasters, held recently in Milwaukee, a paper was read denying the specific value of any special climate in the cure of disease. The author of the paper, Dr. W. H. Wilson, is reported to have said that "the claims made by promoters of certain health resorts that the richness of the air in ozone, the resinous gases from the pines, the peculiar purity of the atmosphere in a particular locality, or the elevation or aridity of the air act as specifics in certain diseases, are not generally based on scientific investigation, but have their origin in the fertile brain of the advertisement writer."

Honors to Armauer Hansen.—On August 10, as we learn from the *British Medical Journal*, a bust of Dr. G. Armauer Hansen, the discoverer of the leprosy bacillus, was unveiled by Professor Visdal in the Garden of the Museum at Bergen, in the presence of many Norwegian and foreign medical men. An address was delivered by Professor O. Lassar of Berlin, and Drs. Sandberg and Lie of Bergen also spoke. Congratulatory messages were sent from all parts of the world, and a letter from Professor Virchow was read, in which the veteran pathologist, after expressing his regret at his inability to be present, went on to say that Dr. Hansen's work had definitively cleared up a large and difficult field of pathology, and that his name was known and celebrated throughout the whole world as a benefactor of mankind. The King of Norway conferred on Dr. Hansen the distinction of Commander of the Order of Ola. He celebrated his sixtieth birthday on July 29.

War on Rats in Japan.—The health authorities in Tokio, in their efforts to suppress the plague, have offered a bounty for the killing of rats in the infected district, with the result that over two hundred thousand of the rodents were destroyed in the course of two weeks in June. As an additional measure, infected buildings covering nearly half an acre were burned.

Baumgarten in Support of Koch.—In a cable dispatch to the New York *Times* it is stated that Prof. Baumgarten of Tübingen supports Koch in his assertion that bovine tuberculosis is not communicable to human beings. Baumgarten describes a series of experiments made by Rokitansky twenty years ago, when patients suffering from incurable tumors were inoculated with bovine tuberculosis germs in the hope that one disease might combat the other. Not a single patient was infected with tuberculosis. Baumgarten believes that bovine and human tuberculosis are not essentially different but that the bacilli suffer modification in the bodies they inhabit.

American Public Health Association.—The twenty-ninth annual meeting of the American Public Health Association will be held at Buffalo, New York, September 16 to 21, 1901. The Executive Committee has selected special topics for consideration, but papers will be received upon other sanitary subjects. Dr. C. O. Probst of Columbus, O., is the Secretary.

The Study of Bovine Tuberculosis.—A Royal Commission has been appointed in Great Britain to study the relation of bovine and human tuberculosis, the object of the inquiry being to determine whether animal and human tuberculosis are identical, whether animals and humans can be reciprocally infected, and under what conditions, if at all, transmission to man occurs, and the means of preventing it if it is proven to be possible. The commissioners are Sir Michael Foster, secretary of the Royal Society; Dr. Sims Woodhead, professor of pathology, Cambridge University; Dr. Harris Cox Martin, Professor J. McFadyean, and Professor R. W. Boyce.

Yellow-Fever Serum.—Drs. Caldas and Bellinzaghi arrived at this port from Havana on Tuesday of this week, having demonstrated the inefficacy of their serum as a means of prevention or cure of yellow fever. They failed to substantiate their claims not only before the Army Board in Havana, but also in the eyes of the Health Officer of the Port of New York, who detained them in quarantine as non-immunes. They are said to be going back to Brazil, where yellow fever exists naturally, and has not to be manufactured to order for the sake of experiments. The man who received an injection of the Bellinzaghi serum before being bitten by an infected mosquito had a sharp attack of yellow fever, but did not die.

Tuberculosis Camps in Wisconsin.—Dr. F. C. Suiter of the Wisconsin State Board of Health has announced that the board is considering favorably a plan for the establishment and maintenance by the State of open-air camps for consumptives in the pineries in the northern part of Wisconsin.

Dr. A. P. Ohlmacher has been appointed Professor of Pathology in the Northwestern University Medical School (Chicago Medical College). Dr. Ohlmacher has been connected with the Pathological Laboratory of the Ohio Hospital for Epileptics at Gallipolis, Ohio, and will for the time being continue the direction of that laboratory.

A Memorial Tablet to the Late Dr. Norman Kerr has been placed on the wall of St. Mark's Church, Hamilton Terrace, London. It is a mosaic illustration of the parable of the Good Samaritan, beneath which is the inscription: "To the memory of Norman Shanks Kerr, M.D., F.L.S., an ardent social reformer and student of the causes and effects of inebriety, who died May 30th, 1899, aged 65 years. This tablet is erected by his family and friends as a tribute to his high character and his unwearied scientific and philanthropic labors."

Typhoid Fever is reported to be unusually prevalent in Baltimore at the present time, fifty new cases of the disease having been reported to the health authorities in the week ending August 31. Acting Health Commissioner Jones is said to attribute the wide prevalence of the disease to the condition of the water supply, which is described as polluted and containing the Eberth bacillus.

Leprosy in St. Louis.—A Chinaman with leprosy has been discovered in St. Louis and the authorities do not know what to do with him. At first it was proposed to isolate him with a physician or nurse to take care of him, and the newspapers had long accounts of the self-sacrifice of a physician who had offered to desert family and practice and to devote himself to the cure of the Chinaman for $50 a month and the opportunity to study leprosy. This plan has, however, apparently been abandoned, for application has now been made to the Louisiana Leper Commission for admittance of the man to the Leper's Home of Louisiana. The application has been refused, and the leper is still in St. Louis. Perhaps they will adopt a plan followed here not very long ago and let the man escape.

A Proposed Monument to Pasteur.—The Commune of Marnes, where Pasteur lived during the last years of his life and where he conducted many of his experiments, has made an appeal to his friends and admirers for funds for a monument to him.

A Congress of "Lay Practitioners of Medicine" is to be held in Berlin in September. The clerical successor of Kneipp will be there, and the mind healers, the faith curists, the electropaths, the magnetic doctors, and all the rest will be there, too.

A New Hospital in the Bronx.—The Sisters of St. Francis intend to build a new general hospital on the block bounded by One Hundred and Forty-second and One Hundred and Forty-third streets and Brook and St. Ann's avenues in the borough of the Bronx. This is directly opposite St. Joseph's Hospital for Consumptives, which is under the charge of the same order. Ground will be broken for the new hospital in a few weeks, the buildings for which will cost about half a million dollars.

Mosquitos and Malaria.—A correspondent sends to the *British Medical Journal* an extract from the journal of the late Alexander Fisher, M.D., R.N., indicating that the connection of mosquitos and malaria was ancient history in the Gulf of California, Mexico, though the proof of the Ajiabambo belief remained to be scientifically established by Manson and Ross. The following is the extract: "July 6, 1864.—Ajiabambo. An anchorage 150 miles down the Gulf of California from Guaymas. Several of the boats communicated with the shore there, their crews landing, and some proceeding inland fifteen miles from the ship to a ranch. . . . Although the appearance of the low sandy bushwood-covered land inland from the beach showed a likely habitat of malaria, one circumstance was pointed out to me as indicative of the absence of malarious poison, which was, that there were no mosquitos, with an assurance that where they do not exist there is no chance of fever."

Obituary Notes.—Dr. William Barnsmore Pape of Mobile, Ala., died at his home in that city on August 30, at the age of fifty-one years. He was noted as a pianist, and when thirteen years of age appeared with Mme. Anna Bishop in New York. He visited Havana and Canada, and made two tours of England, playing before the royal family in 1864. Later he took up the study of medicine, and was graduated from the Medical College of Alabama, in Mobile, in 1882.

Dr. George William Wells, editor of the *Medical Examiner and Practitioner*, and medical director of the Manhattan Life Insurance Company of this city, died at his home in Richmond Hill, L. I., on September 3. He was born in Tyrone, N. Y., in 1841, and received his classical education at Princeton, from which college he was graduated in 1865. He obtained his medical degree from the Bellevue Hospital Medical College in 1868, and later studied at the Long Island College Hospital. Upon beginning practice in this city, he was for a time attending physician to the out-patient department at Bellevue, but he soon took up life-insurance examination as a specialty, retiring then, of necessity, from active practice.

Dr. Robert Barnwell Rhett, Jr., of Charleston, S. C., died in that city of typhoid fever on August 7 at the age of forty-seven years. He was a graduate of the Medical College of the State of South Carolina, in the class of 1879.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GOSSIP FROM CHELTENHAM'S RETURNED GUESTS—CANDIDATES FOR THE GENERA LMEDICAL COUNCIL—MIDWIVES—DEATH OF SURGEON-GENERAL FRANCIS.

LONDON, August 9, 1901.

JUDGING from the gossip of those who have returned, the Cheltenham meeting seems to have been successful. There is gratulation among the leaders that the scheme for reorganization passed so easily. On the other hand, there are misgivings in other quarters as to the results. The changes have been accepted with scarcely any reservation, and now it only remains to carry them out. They are so many and of so little interest to outsiders that you will not care to give space to an enumeration of them. The Guide prepared for the occasion, and two or three other pamphlets, one of them quite an album of illustrations, gave every information about "the Garden Town" and its claims as a health resort. The dinner, usually a noisy affair, was noisier than ever; but the guests were on good terms with themselves, and the noise was not directed against obnoxious individuals, as I remember on some occasions it was.

In the military and naval section, Sir Wm. MacCormac read a paper in which he referred to "amateur critics who had no idea of perspective and exaggerated everything." The reporters for the daily papers applied this to Mr. Burdett-Coutts, though his name was not mentioned. Mr. Coutts has, in consequence, rushed into the *Times* with a letter full of "sound and fury signifying nothing," except abuse of Sir William and the army service, and a repetition of his already refuted misstatements. His anger blinds him to the fact that his unsupported assertions have no importance since the Royal Commission exposed their want of truth. Sir William will, no doubt, survive the attack of a furious distributor of slander. But what of Mr. Coutts himself? Can he imagine that making himself notorious will confer on him fame?

The breakfast given by the National Temperance League for a number of years past has become quite an interesting feature of the British Medical Association's meetings. This year it was followed by a temperance meeting in the evening, at which several members put in an appearance. The speeches at these functions supplemented each other. Dr. Kelynack insisted on the scientific aspect of the temperance question, and urged that science, like justice, must have "the truth, the whole truth, and nothing but the truth." Mr. Eccles, as a surgeon, would not speak for physicians, but declared emphatically that alcohol was useless in surgical cases. He thought it of value in certain scientific experiments, but not to give to patients; if ever it was necessary to physicians, they should not send it out in grocers' bottles, but in proper doses, like other dangerous drugs. Dr. Ridge "went for" those doctors who prescribe it to patients who would rather go without it. Dr. James Stewart made an earnest appeal to parents not to put temptation before their children. Dr. C. R. Drysdale urged that drink was unnecessary, as proved by the number of clever men who never touched it. He made also the very interesting statement that his own mother lived for one hundred years without having tasted it. That lady's century covers the period when almost everyone held that it was necessary for health, and goes back to the time before abstinence was widely advocated; her experience, therefore, was probably rare.

The speeches of candidates for the Medical Council were not very encouraging to ardent reformers. Dr. Glover remarked that it will not be possible to obtain more direct representatives until three-fourths of the profession no longer abstain from voting. It did not seem to occur to him or the other speakers that the whole scheme of direct representation never can be of real service. It was in its time pushed with every electioneering dodge by the British Medical Association in opposition to a more practicable plan of reform. Success so far resulted that we have this greatly advertised panacea direct representation, and it has done nothing for us, has not even sent to the council a trio of members unanimous on main issues.

On such a subject as the usurpation of authority by the Obstetrical Society, they did not represent the profession. When the council as a body determined to put an end to that usurpation, what happened? An ignominious surrender to the leading Fellows of that society, a trifling revision of their sham diploma, which is doing as much harm as ever. Had the council then stuck to its guns, the present position of this troublesome midwives' question would have been more satisfactory. Dr. Glover hardly gauges the opinion and feeling of the profession on this point. He dare not support the Obstetrical Society, and holds that it can be replaced only by some board acting under law. Hence he has supported the set of busy-bodies who are calling for legislation in this or that direction—one set agitating for one thing and another set for something else. The set that has obtained government promises seems to have inspired terror into all parties. Dr. Glover rather chaffed Mr. Brown that he had not in the council moved to disapprove all attempts at legislation, as probably he would not get a seconder. The taunt may or may not be quite fair from the colleague who opposed him, but it clearly proves what I have said, that the so-called direct representatives do not really represent the profession, but only their own opinions. With three such members some of the public would say they do exactly represent the hopelessly divided views of the doctors.

Mr. Victor Horsley is a vigorous member of the council, and has done yeoman's service. He would have sent a protest to the Privy Council on the treatment measured out to its recommendations and the other slights of government, but could not carry his resolution, as was the case with other proposals of his. He spoke out clearly at Cheltenham, and on some points will meet support. He has done much good in exposing the unsoundness of the council's finances. But he suggests that every registered practitioner should be further mulcted £1 every year. Probably these practitioners will agree that if the council has squandered all the money taken for registration and reached a state bordering on bankruptcy, considering the little it has done for us, we should find it cheaper, better, and less vexatious to dismiss a body which has been found wanting on all important occasions.

Mr. Horsley is also willing to enter on the thorny path of midwives' legislation, and apparently thinks it would be practicable in some degree to control the intentions of those who are appealing to Parliament. It is a sanguine view to take. Once the legislature is engaged on a bill, the screams of hysterical women will have more influence than the reason of sober doctors.

Writing of the Obstetrical Society and the divisions of doctors reminds me that a new gynecological journal is being arranged for, and this fact is bringing into prominence the antagonism between the two societies in London. The obstetric section of the profession has generally been credited with being its most quarrelsome branch, and the suggestion was well kept up when the younger started and its elder blackballed candidates who belonged to the junior.

Then last year you may remember how the jealousies of this branch defeated the project of holding the International Congress in London. The present scheme of a British and colonial journal of obstetrics and gynecology seems to have taken its origin in the northern counties, and to be for some time confined to the provinces in order to steer clear of the jealousies of the two London societies. To a large extent the plan seems to have succeeded, though it will not be easy to appease all susceptibilities. However, the men of the North will not give up their plans, and whatever the case at the outset, we may be sure they will conquer in the end. You may, therefore, look for the appearance of a journal worthy to rank with that of America or Germany.

The death is announced of Surgeon-General Francis, who had a distinguished career, serving in the Crimea and in India. He retired some years ago, and was well known in London.

THE PLAGUE IN CONSTANTINOPLE.

(From Our Special Correspondent.)

AUGUST 14, 1901.

As previously stated, official notice was recently given that ten days having elapsed since the declaration of a "suspect"—as the word goes now for plague—and the public health being declared perfect, clean bills of health were to be issued, a matter of great rejoicing. But, and alas! on July 4th two more "suspects" were reported, and up to July 10th a few more cases, scattered over town and suburbs, and also in villages on the Bosphorus. The vagaries of quarantine were again repeated—Greece, as usual, leading the law—Roumania, Servia, and other Balkan States following.

On July 27th Mr. W. H. Beach, an expert on Indian plague, arrived in this city. This gentleman has been engaged by the Turkish Government to assist with his clinical experience the Municipal Medical and Hygienic

Council, presided over by Redvav Pacha, the prefect of the city. This council is entirely apart from the International Health Board. Surprise is expressed at this engagement of Mr. Beach, as Turkey has not lacked first-rate specialists in her service, and especially prominent bacteriologists, such as Chantemesse and Nicolle. He has been definitely attached to the sanitary service of the prefecture, takes part at the sittings, has visited the Lazaretto at Kavak, the "lands," or water reservoirs, and various parts of the city. It is currently reported that he has expressed a fairly favorable report on the healthiness of Constantinople, and this is justified, as there is certainly, so far, less enteric fever and fewer gastric affections than usual at this season. Thus far, as is stated, plague has been bacteriologically proved in some of the cases. But who can enumerate or explain the numberless "iradés" and "ordinances of hygiene"? The International Health Board, with its odd composition of doctors, dragomans and other employees of embassies, legations, and consulates, and officials of the Porte and Palace, puts on and takes off quarantine at its own will, or the will of somebody else, and seldom, if ever, has set its foot against the panic-stricken action of these minor States, which have all accepted, but do not practise, the doctrines of modern sanitary science, and show little disposition to abandon very antiquated methods, probably because they know how well they are prepared for, but not against, cholera or plague. One ordinance involves a change of commercial and social interests. This must be accepted and arranged for. Scarcely does it enter into operation than forth issues another circular modifying or annulling the previous one. Commercial and social conditions of the age do not readily adapt themselves to such changing regulations.

The municipal regulations and palace "iradés" called forth by these scares go at all classes and conditions of life—barbers, butchers, bakers, proprietors of restaurants, pharmacists, heads of slaughter houses, publicans, and sinners of every degree and profession. Even a doctor has fallen under the municipal ban, and has been incarcerated in his own house for having visited a "suspect." Fortunately for the general health of the city, the summer has been unusually rainy, and the very heavy rains of the last two weeks have done more to secure the public health than any amount of municipal efforts could ever do. The air and streets were well washed, and the public drains flushed to such an extent as to clear them of rats, which were carried drowned to the sea. But these drowned animals are pointed to by timorous officials as serious evidence of the presence of plague.

The total number of "suspects"—call them not yet cases of plague—is reported to have been sixteen, with two deaths, extending over a period of nearly six months since the first case occurred. To-day two cases are reported as having occurred in "Balukbazaar" (fish market). This is an eminently dirty quarter, and if plague be located there, washing with disinfectants would give an object lesson of inutility. The cases have been removed to Kavak, and have been visited by Mr. Beach, who, it is stated, considers them true plague. How they were treated beforehand it would be interesting to know. The municipality has received a considerable supply of Yersin's serum from the Pasteur Institute of Paris. Was it injected in any of the cases before the bacteriological examination? Nothing short of accord between the clinical evidence and bacteriological examination will satisfy public opinion that plague has been clearly proved to exist. The fact is that intelligent public opinion here is in advance of both international and municipal action. The teachings that pestilence and dirt are closely associated, and that the spread of epidemics, sooner or later, becomes a question of local conditions—especially so with plague, against which quarantine laws were originally instituted and also that plague is not more readily communicated than other infectious diseases, have made way even in Turkey. It may be that we are on the eve of an outbreak of plague; therefore the municipal precautions, imitative in many respects, are praiseworthy. The engagement of Mr. Beach, as an independent authority, is to the credit of the Turkish authorities.

Again, the two sanitary administrations, *i. e.* the international and the municipal, are showing signs of antagonism. The municipal body sends its true or suspected cases to the quarantine establishment at Kavak. The International Health Board properly objects to this in the interests of the shipping, inasmuch as the lazaretto may become an actual focus of infection, endangering Europe generally. On the other hand, the municipal body has no infectious hospital to which the cases can be sent. It is now proposed to establish one. By the time this is accomplished, if ever, plague will have probably ceased for the time, and the scheme will then remain in abeyance till there is another scare.

In the meantime, the quarantine measures have brought about such a paralysis of commerce that it is a local question whether more is to be feared from them than from plague itself. Servia is very active and severe. She prohibits sugar, rice, butter, fruits, cheese, meat, caviare, cereals, fish, coffee, as possible carriers of plague. The fact of passengers having "purged" quarantine at Hebitchovo is not considered sufficient. The Oriental Express is allowed to proceed on condition of all the windows being hermetically closed, and that no passenger may descend from the train. Of course, passengers cannot risk such a disagreeable journey; and all this in spite of the declarations of the Dresden Congress in 1893, and that of Vienna, in 1897, that land quarantines are absolutely useless and inefficacious.

The measures decreed by the "Administration Sanitaire de l'Empire Ottomane," applicable to travelers leaving Constantinople (date July 27th), are curious. They might apply to escaping criminals, but not to respectable citizens and travelers.

LETTER FROM NEW ZEALAND.

(From our Special Correspondent.)

AUCKLAND, July 27, 1901.

THE plague scare is over as regards New Zealand, and although there are still a few cases reported in Australia, nobody seems to worry about them. It is curious to notice the complete indifference of the public, as compared with the frenzied excitement of last year.

The profession, as well as the public, have been greatly agitated lately, by a coroner's inquest on a Mrs. O'Dowd, who died under very extraordinary circumstances in May. It appears that Mrs. O'Dowd, who had only been married on the 11th of April, died on the 17th of May of septicæmia and peritonitis, occurring subsequent (as she stated) to an operation performed by one of the best-known surgeons in New Zealand, for the purpose of procuring an abortion. From the purely medical point of view, the evidence given before the coroner and subsequently before the Stipendiary Magistrate was very curious. It appeared, from the sworn evidence, that on Wednesday, May 15th, at 2 P. M. the deceased was certainly to all appearance perfectly well; that shortly after that time she went out and returned at 4.30 or thereabouts; that she then had tea with one of the women residing in the house—she and her husband kept a hotel—and that she told this woman that she had been to a surgeon whom she named, and who had performed an operation for her. She went to bed apparently quite well, but at 8 A. M. on Thursday (16th May) as she did not come down to breakfast, her husband went up to her room, and found her standing on the bed doing her hair. While he was speaking to her about breakfast, she fell suddenly on the bed in a kind of swoon. She said that she had a bad headache, and that she should be better after a cup of tea. All that day she kept her bed complaining of pain in the head and abdomen, but refusing to allow a doctor to be sent for, until nearly 8 P. M., when she was screaming with pain, and her husband telephoned for one of the physicians in this city. He came soon after 8, and was informed of the visit and the operation. He examined the patient and gave her an opiate, which gave some relief to the pain. Her temperature was 103° F., and she showed distinct symptoms of peritonitis. Between 11 and 12 that night he saw her again; she was much worse and said, "I am dying, I am dying, give me some chloroform." On this occasion, I think it was, that the visiting surgeon used Sim's speculum, and made some local applications to the uterus. He gave her another opiate and said he would call about 7 the next morning, unless he were telephoned for earlier. At 4.30 the next morning he was sent for, and reached the house at about 5, only to find his patient *in articulo*. She died at 5.10, having been unconscious for some time.

At the autopsy, made the same day (Friday, 17th) at 3 P. M., the whole of the peritoneum was found intensely congested, a pint of blood was in the pelvis, and a three months fœtus in the uterus. Decomposition had already gone so far that there was actually emphysema of the skin, and the face of the deceased was quite black from decomposed blood. The cavity of the uterus contained no liquor amnii; there was no lesion of the vagina, uterus, or its annexes. There was no other morbid appearance that could account for death. No microscopical or bacteriological examination of the blood was made.

The deceased had told the physician last called that she had been to the surgeon before referred to and that he had put an instrument into her, of what kind she did not know, as she was lying on her back. It may be remarked that the surgeon denied on oath that she had been to see him that day, and produced three other witnesses whose evidence covered the whole of the time that she said she was with him and who stated that she was never there. One young man who had an office in the same building as the surgeon swore that he had seen her there on the afternoon of the 15th, but on cross-examination admitted that he could not be absolutely certain, as he only saw her side-face. The curious feature of the case is the extraordinary rapidity of the blood poisoning, if, as asserted by the medical witnesses for the Crown, the septicæmia arose from the dead fœtus, and the fœtus was killed by, or in consequence of Wednesday's operation. A period of thirty-nine hours only intervened between the operation and the death. The verdict of the coroner's jury was that death resulted "from septicæmia caused by violence to the uterus, but how this occurred there is not sufficient evidence to show." Very much to every one's surprise the next day after the inquest had closed, the surgeon was arrested on a charge of murder, and brought before the Stipendiary Magistrate. The same evidence was brought forward as at the inquest, and the magistrate committed him for trial at the next criminal sessions. There is no doubt that he will be acquitted, as no judge will admit as evidence what the deceased woman stated, not on oath, and not subjected to any cross-examination. It seems to me that the fœtus must have been dead long before the Wednesday, 15th of May, on which the operation was alleged to have been performed. The invariable practice of these women, before they apply to a medical practitioner, is to take medicines, and only when these fail, do they desire an operation.

The practice of criminal abortion is exceedingly common here, and women frequently operate on themselves with disastrous results. It is very rare for a conviction to be obtained, as the popular sympathy, especially of the female part of the community, is almost invariably with the accused party. The punishment is far too severe, and juries acquit men and women, not because they think them innocent, but because they think imprisonment for life for administering abortifacients is too harsh a penalty. And to charge a person with murder, who had not only no intention to kill, but whose strongest interest and wish was that his patient should recover, seems to non-legal persons an outrageous misuse of words.

But for an old gentleman of seventy, with a grown-up family and grandchildren, to be accused of and tried for murder is a terrible punishment, even if he be acquitted.

Intraligamentous Cysts.—C. D. Palmer (*Cincinnati Lancet-Clinic*) gives the following diagnostic points: (1) They are lower than usual in the pelvic cavity. They may extend from their base outside of the peritoneal cavity, to between the uterus and rectum or bladder. (2) They are more or less connected with, and adherent to, the uterus. (3) They are smaller relatively in size, have fewer daughter cysts, and have a slower growth. (4) They often displace the uterus to the opposite side, and may make it immobile. (5) They are more apt to press upon the bladder, and obstruct the rectum. (6) They are more apt, by intrapelvic compaction, to compress the ureters, causing hydronephrosis. (7) Intestinal adhesions are not uncommon, from a secondary infected peritoneum. (8) So, too, there are increased chances of their infection from a septic uterus or intestines, hence, oftentimes suppuration of their contents. (9) Not unfrequently are they bilateral. (10) Usually they are papillomatous, proliferating; these papilla may rupture the cyst wall, and lie free in the peritoneal cavity, and they then grow on neighboring organs. Hence occurs metastatic infection of the peritoneum.

Mechanical Constriction of the Uvula.—W. E. Hadden has reported a case in which the uvula became accidentally constricted by a bit of thread, causing distressing symptoms of vomiting and retching. The patient was a linen weaver. Relief was afforded by snipping off the swollen part with scissors.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 22, 1901.

The Indications for Operation in Gastric Ulcer.—Arthur T. Cabot discusses, first, the various operations which are resorted to in the treatment of ulcer of the stomach, and the objects for which they are employed. These are: (1) Gastrotomy, including the excision of ulcers; (2) gastroplication, or turning in of the stomach wall to close an ulcer that has perforated or to strengthen the wall at a point where perforation is threatened; (3) pylorectomy, for the removal of an ulcerating pylorus; 4 pyloroplasty for the widening of a pylorus contracted by ulceration; (5) gastro-enterostomy, to provide a short cut into the intestine from a stomach whose motility is interfered with by ulceration. Briefly stated, the indications for surgical treatment are: 1. Acute hemorrhages should rarely be treated by operation; the results of interference have not been good, while the results of medical treatment have been satisfactory. When, however, a hemorrhage frequently repeats itself, even if severe in amount, it will demand operative treatment as soon as its recurrent character is plain. 2. Small, frequent hemorrhages, threatening anæmia, give a clear indication for operation. 3. Perforation of the stomach, either acute with general peritonitis, or chronic with surrounding adhesions and perigastritis, demands instant operation. 4. When an ulcer runs a chronic course with a strong tendency to recurrence, and gradually diminishes the patient's capacity for work and for the enjoyment of life, an operation is indicated, especially when the patient is so situated as to be dependent on his daily work for support and unable to closely regulate his diet.

New Procedures in the Treatment of Hip Disease.—E. H. Bradford reports a case of acetabular disease of the hip joint in a boy of six years, in which the disease made such steady progress that the question of exsection came up. An *x*-ray examination, however, showed that the acetabulum was the part chiefly involved, hence removal of the head of the femur would be of little use. Excision of the acetabulum was not deemed justifiable because of the high rate of mortality attending this operation, and the parents would not consent to amputation at the hip. The following procedure was therefore adopted: The head was thrown out of the joint by means of incision similar to that for excision and placed upon the dorsum of the ilium. A free incision was made, allowing free drainage from the acetabulum, which was found perforated; a celluloid drainage tube of an inch in diameter was inserted to a sufficient depth to reach the acetabulum, and secured by a stitch; the base of the acetabulum was touched with carbolic crystals and washed off with alcohol. The limb was then fixed in a plaster-of-Paris spica in a position of the limb assumed in hip disease in the stage of deformity; that is, flexion and adduction. Marked improvement took place in the condition of the boy. He required no opiates, was able to move without pain immediately after the operation, and in a few weeks was able to walk about on crutches. The drainage was kept up for six months, after which time the plaster was removed, and the boy was allowed to go about with the limb moving freely.

New York Medical Journal, August 31, 1901.

The Œsophagometer or Intragastric Whistle.—C. D. Spivak describes an instrument by means of which he claims to be able to determine with precision the length of the œsophagus in any given case. The device consists of a stomach tube provided at its distal extremity with a whistle so placed that the opening through which the air is blown in looks toward the proximal end, while that through which the air makes its exit is in apposition with the side opening of the tube. The tube is introduced into the œsophagus, and air blown in. So long as the whistle traverses the œsophagus the instrument is smothered and no sound is heard; but as soon as the cardia is reached a distinct whistle is heard. The tube can be pushed forward and backward several times so as to ascertain the exact point at which the whistle becomes audible. The distance between the distal border of the side opening of the tube and the point at the incisor teeth where the whistling sound is first heard represents with precision the distance between the incisor teeth and the cardia.

The Diagnosis, Etiology, Prophylaxis, and Treatment of Cystitis, Pyelitis, and Pyelonephritis in Women. Thomas R. Brown says that most of these diseases are due to infection with various microorganisms of which the colon bacillus is the commonest; which may reach the kidney or bladder either exogenously or endogenously. These diseases can usually be prevented or cured if the conditions underlying their development are recog-

nized and understood, and the correct measures inaugurated. There are various conditions, such as urinary hyperacidity, which may simulate almost exactly true vesical infections, and yet in which misinterpretation and improper treatment may lead to the development of a true cystitis. In no condition is prophylaxis more essential than in that of the infections of the urinary tract, and we must have constantly before us the danger of infection when the general resistance of the patient is lowered. An absolute diagnosis of renal infection can be made only by ureteral catheterism, but usualy a very probable diagnosis may be arrived at by a consideration of the relation between the grade of albuminuria and pyuria and by careful cystoscopic examination of the bladder. A great majority of the infections both of the bladder and of the kidney are associated with acidity of the urine—that is, are due to microorganisms which do not split up the urea. Probably in the majority, if not in all the cases of renal infections due to a urea-decomposing microorganism, after the condition has lasted for a certain length of time, a stone is formed by the decomposition of the precipitated salts about the bacteria as a nucleus. Finally, one who would thoroughly understand and successfully treat these cases of cystitis, pyelitis, and pyelonephritis must remember that a careful chemical, microscopical, and bacteriological study of the urine is absolutely essential.

Medical News, August 31, 1901.

Fatal Cases of Pemphigus and Erysipelas in Infants.—Frank S. Meara reports a case of fatal pemphigus in a child seven months old, previously healthy. The autopsy revealed areas of congestion in the lungs, patches of congestion in the small and large intestines, with deep congestion of the mesenteric vessels near the patches. The second case was one of erysipelas migrans in a three-months-old baby. In discussing the etiology, Meara regards the two conditions as due to the same germ, which produced the apparently varied diseases because of modified metabolism, gaining entrance through the skin or alimentary tract. He also believes that the most varied manifestations of infection may occur in the body from identical or similar germs, always present, seizing their opportunity for development when some error occurs in the body functions.

The Racial Factor in Hysteria.—Julius Ullman concludes that hysteria is seen amongst all people and in all countries, and the fact that it affects certain races more frequently, like the Jewish and Latin races, may be attributed to causes of environment rather than inherent qualities of a race. Heredity plays a rôle only in that the child may learn to imitate certain traits of its parent, the environment and habits remaining the same. The hysterical background which may be an epiphenomenon in certain organic diseases in the Slav, Latin, and Jewish races must not be overlooked; nor, on the other hand, must the fact be lost sight of that organic disease may at the same time be present with well-marked symptoms of hysteria. Better therapeutic results will often be obtained among the susceptible races by measures directed against a latent hysterical condition in addition to the treatment for such organic disease as may be present.

The Drug Habit; Its Cause and Restriction.—Joseph M. Atkin believes that modern civilization either produces more and greater pains or else the people are less tolerant, and that the present requirements for business and social conditions increase the demand for and lessen the resistance against narcotics. While morphine claims by far the greater number of habitués, cocaine and the coal-tar preparations, as well as many other drugs, also command their slaves. He thinks those are to blame for the formation of drug habits who place the remedy at the disposal of all who apply, without also providing adequate instruction as to its baneful effects. It occasionally happens also that a doctor unwittingly lays the foundation of a drug habit by not impressing the patient with the fact that he must not renew the prescription without permission. While liberal education of the people will do something toward remedying the formation of drug habits, the principal aid is to come from the physician who, knowing drugs and their uses, must employ them in their widest sense for liberating and not enslaving human beings.

Journal Am. Med. Association, August 31, 1901.

Intrauterine Amputations.—J. Maher reports the case of a baby born minus some fingers and toes, on examination of whom, some fifteen hours after birth, he found constricting bands of what appeared to be dried fibrin encircling several of the fingers and toes, and evidently doing the amputating. The causes of intrauterine amputation, as given by the textbooks, are Amniotic bands, inflammations, intrauterine fractures, and constrictions by the cord. The author says that it is reasonable to assume that the amniotic bands, so called, might be due to fibrin deposited upon a part from the liquor amnii in the same way that it is deposited by whipping fresh blood. The fibrous bands so formed would constrict the part, causing arrest of development beyond the point of constriction, and subsequent amputation.

Ancient and Modern Conceptions of Syphilis.—William L. Baum reviews briefly the history of this disease from the time of the Naples epidemic, in 1494, to the present time. The earliest conception was that the affection was a new disease resulting from the conjunction of the planets Saturn and Mars. This was later followed by the theory that it was a veritable pestilence caused by the floods which occurred all over Europe in the spring and summer of 1494. The animalcular theory began to assume prominence early in the seventeenth century. It was not until the eighteenth century that the different diseases charged to venery began to be distinguished one from the other, but the demarcation between hard and soft chancre, which even yet is not accepted in its entirety by all, was not established until 1852. Bassereau, a pupil of Ricord, was the one who demonstrated the duality of these diseases. The problems yet to be solved are: The early diagnosis of the disease where the primary sore is either not recognized, as in extragenital syphilis, or when it is abnormal; the determination as to what predisposition produces the serious nervous and other consequences of tertiary lues, and a determination of the predispositions leading to the parasyphiloses. The next thing is to determine the influence of other diseases, whether malign or benign, upon syphilis; and the bacteriology and bacteriomorphology of lues remain to be worked out.

American Medicine, August 31, 1901.

How to Give Epsom Salts.—W. E. Putnam advises the following method of taking Epsom salts so as to avoid the taste: Use just enough water to completely dissolve the salts. From a second glass full of plain water drink two large swallows, take the salts quickly and drink the rest of the water in the second glass. He has suggested the putting up of magnesium sulphate tablets, five and ten grains, without coating.

The Value of Antitoxin in Diphtheria.—Walter R. Griess divides the cases of diphtheria into two classes: those appearing favorable in the beginning, showing moderate intoxication, and those of intense intoxication with rapidly spreading local manifestations. Antitoxin acts by rendering the toxins of the bacteria non-effective, but does not affect the bacteria themselves, hence the necessity for additional treatment in the disease. The writer concludes that antitoxin should be given as soon as the diagnosis is made with certainty. Larger doses are required by children. In mild cases of diphtheria, 2,000 units should be the initial dose, repeated in twelve hours if no improvement takes place. All laryngeal cases or cases with severe prostration should have 4,000 units as an initial dose and 2,000 units within twelve hours again if there is not marked improvement. Intubation in children should be practised before exhaustion occurs, followed by tracheotomy if the first operation is not successful, the operations being preceded by the administration of a stimulant. The results of antitoxin are governed by the type of cases in which it is employed and whether it is employed late or early in the course of the disease.

Philadelphia Medical Journal, August 31, 1901.

Traumatic Hysteria; Operation; Recovery.—Frank R. Fry reports at length a case of traumatic hysteria which came under his own observation and in which he operated successfully. He concludes that, while no rules for operation can be formulated, if in any case there is doubt as to the traumatic origin of hysterical symptoms, or the possibility of surgical relief, the patient should have the benefit of this doubt, and an operation should be performed, and that the case should be thoroughly investigated from a neurological standpoint.

Sweat Baths and Baths Which Increase Bodily Temperature. R. Friedlaender prefers temperature-increasing baths in combating infectious and toxic conditions: (1) In acute and subacute diseases due to exposure, catarrh of the upper respiratory passages, fresh rheumatic affections of the muscles and joints, and also in other infections, the onset of which is not characterized by high fever, and in which the individual conditions render an increase of the fever permissible and desirable for the course of the pathological process; furthermore, in syphilis and in general gonorrheal infection. (2) When an intense increase of metabolism is indicated for other

reasons, such as autointoxication, and in conditions affecting metabolism, like gout. He favors sweat baths (1) when a cure by means of free diaphoresis is contemplated; in exudations and transudations, in nephritis with œdema, in hydræmia and chlorosis, in metallic poisoning, and in obesity as an adjunct to other methods of treatment; (2) when chronic inflammatory processes are to be influenced by peripheral hyperæmia. In chronic and especially rheumatic affections of the muscles, joints, and nerves, in the residual conditions of acute articular rheumatism, in chronic muscular rheumatism and arthritis deformans, in neuritides, and in tuberculous arthritic affections.

The Lancet, August 24, 1901.

The Treatment of Melancholia.—H. de Maine Alexander divides this disease into two stages, acute and subacute, preceding recovery or a fall into the chronic state, and sums up the symptoms characterizing the two stages, as follows: "A. *Acute Stage.*—1. Mental symptoms: great depression, restlessness, vivid hallucinations, and sleeplessness. 2. Pulse rapid, from 90 to 120 per minute, of high tension, and tending to be irregular; arterial pressure high (from 140 to 180 millimeters of mercury). 3. Temperature tending to be febrile (from 99° to 100° F.). 4. Urine scanty; excretion of urea deficient; trace of albumin present. 5. Tongue furred and foul; no desire for food or drink; digestive power of stomach upon coagulated albumin practically *nil*, motor power of stomach weak; bowels constipated and stools very offensive. 6. Skin dry. B. *Subacute stage.*—1. Mental symptoms less acute; the patient generally sleeps well; hallucinations, if present, do not affect conduct. 2. Pulse regular, softer, from 70 to 80 per minute; arterial pressure from 120 to 130 millimeters of mercury. 3. Temperature never above 98.4°. 4. Urine more abundant, excretion of urea considerably increased; albumin never detected. 5. Tongue clean; appetite for food and drink returning; digestive power of stomach juice at first weak but later active; tendency to constipation less marked. 6. Skin becoming moist; sometimes perspiration profuse." As to the therapy of the disease, the author believes that melancholia is a disease of disordered metabolism, and that treatment should be directed toward increasing the excretion of waste products of this metabolism through the channels of the urinary and integumentary systems. He mechanically accomplishes this end by administering to his patients an abundant fluid dietary. By means of this treatment the blood gets rid of its overcharge of waste products, and the arterial tension falls. He assists digestion by giving milk frequently, and in small quantities, as it is the most easily assimilated food. He considers the forcing of solid food (or such food as custards) upon a patient suffering from acute melancholia just as injudicious treatment as would be the feeding of a patient suffering from typhoid fever exclusively on beefsteaks.

Inunction vs. Intramuscular Injection in the Treatment of Syphilis.—C. F. Marshall presents a comparative table of sixty-nine cases of syphilis, in thirty-seven of which mercurial intramuscular injections were employed, in thirty-two inunctions. When the active symptoms had cleared up, the patients were put on a course of pills—as a rule, two grains of blue pill twice daily. The method of intramuscular injection employed was that introduced by J. A. Bloxam. Ten minims of a solution of sal alembroth, containing one-third of a grain of the salt, were injected by means of a platinum-iridium needle deeply into the muscles of the buttocks. The injections were performed once a week into alternate buttocks. The inunction was done with unguentum cinereum, consisting of one part of mercury, one part of lanolin, and half a part of olive oil. About half a drachm of this was rubbed daily into different parts of the body. The rubbing lasted twenty minutes. A warm bath was taken before each inunction.

As to the results of the treatment, the table shows that there were sixteen relapses of the disease during or after treatment by intramuscular injection, including four cases of severe iritis and one case of early tertiary syphilis. Out of the thirty-two cases treated by inunction there were seven relapses (two of which were doubtful) and one case of iritis. As nearly all of these cases were under observation in hospital for a year or more, the author thinks it is justifiable to draw the conclusion that relapses are twice as frequent with the injection treatment as with the inunction method. The advantages claimed for injection are secrecy, cleanliness, uniformity of dose, and that it is performed by the surgeon himself; the disadvantages of inunction are its irksomeness and dirtiness. The writer holds, however, that inunction is the more reliable method of the two, and that it is the best where rapid mercurialization is required, as in cases of iritis. The great objection to the intramuscular injection of perchloride of mercury is the pain caused by it, which is often considerable. Injections of sozoiodol of mercury or of Lang's gray oil are said to be less painful.

British Medical Journal, August 24, 1901.

Case of Tetanus; Recovery under Chloral.—J. Thomson Shirlaw reports a case arising from an acute spreading gangrene following a severe compound fracture of the leg, complicated by simple fracture of the thigh on the same side. The treatment consisted in keeping the patient fully under the influence of chloral, carefully watching its effects; thus thirty grains were given usually every two hours, varied by an interval of three hours, or a double dose, according to the severity of the tetanic seizures. The case was under observation nearly two months, the feeding throughout the duration of the tetanus being done by a tube.

Healthfulness of Modern Warships.—W. E. Home concludes that a ship to be healthful must allow 120 cubic feet of space per man, more in the tropics; there must be uptake elevators from every compartment, opening near the top and easily cleaned; cowls and air shafts are needed for hatchways, and windscoops for all ports and scuttles; artificial ventilation is required for all living space. The ship should be warmed and kept dry by steam radiators. Decks after washing should be washed over with an antiseptic solution, also mess tables and stools should be treated in the same way. There should be a drying room for garments and bedding of the ship's company.

The Theory of Air-borne Typhoid in Armies.—H. E. Leigh Canney considers in detail the conditions under which typhoid fever originates and spreads in India, South Africa, and Egypt, concluding that the evidence of air-borne typhoid recorded in Indian military experience is not established; that in South Africa and Egypt the evidence is opposed to this theory, and that in all three countries the weight of evidence and probability is in favor of a water-borne origin and spread. The evidence from Egypt proves that if water be protected, all other avenues are powerless to originate and spread typhoid in large bodies of men, and the presumptive evidence is strong in the same direction with regard to India and South Africa. The theory of the origin and spread of typhoid fever by flies and dust is *only* a theory; it can only be discussed as such with relation to laboratory experiments, and should not hinder the adoption of vigorous measures against water-borne typhoid.

Treatment of Dysentery.—W. Rous Kemp gives the following account of the treatment of dysentery in Natal. Nourishment consisted of white of egg beaten up with soda water; this appeases the appetite, nourishes the patient, and not upset the stomach. When the stools were reduced does to seven in twenty-four hours, an ounce of raw beef juice with the same amount of port wine three times a day was added to the eggs, of which twelve to eighteen were taken in twenty-four hours. Lime juice sweetened and mixed with soda water was used as a beverage with great success. The local treatment consisted of a warm saturated solution of boracic acid night and morning. For severe tenesmus the internal sphincter was swabbed with a two per cent. solution of cocaine, and tormina was relieved by hot fomentations with a few drops of turpentine. Hiccough and vomiting can usually be controlled by allowing the patient to suck ice and administering every half-hour: Vin. ipecac., ℥j.; tr. nucis vom., ℥ii.; sp. chloroform, ℥x.; aq. ad., ℥i.

Berliner klinische Wochenschrift, August 12, 1901.

Cataract Operations in Old Age.—F. Mendel says that even in those advanced in years extraction is to be preferred to other less radical procedures. Usually it is advisable to remain satisfied if vision has been restored to one eye without attempting a second operation on the other. Out of thirty-six extractions on patients over eighty years old, thirty-four recoveries with satisfactory vision are reported, equaling a percentage of 94.4, a figure that should satisfy both operator and patient. Bronchitis with the attendant strain of coughing is the most serious complication, and often requires protracted treatment before operation is safe, while careful nursing is a prime requisite during convalescence. Post-operative delirium is not infrequent, but usually yields readily to narcotics.

The Pathogenesis of Delirium Tremens.—K. Bonhoeffer's conclusions are based on a material of 252 cases observed in the Breslau clinic. Of this number it was found that in seventy per cent. there was some complication, either immediately preceding the onset of the delirium or attendant on it. Of these, the diseases of the respiratory tract and especially the

acute infections have the greatest etiological significance, and gastro-intestinal affections occupy the second place. Trauma seems to possess but slight importance, and appears to have influence only in the direct or indirect (possibly through fat embolism) effect it may have on the respiratory apparatus. Epileptic attacks, in so far as they are not themselves a manifestation of the same toxic process underlying the delirium, distinctly predispose to its onset, particularly in connection with alcoholic excesses. Sudden withdrawal of alcohol, in spite of the observations of Smith and others, is capable of bringing on the attacks, especially if malnutrition is also a factor; such forms often run a short or abortive course and do not offer a grave prognosis.

The Use of Subcutaneous Injections of Gelatin as a Hemostatic.—Grunow reports on the use of gelatin solution hypodermically in twenty-seven cases, comprising respectively seven of pulmonary hemorrhage, eight of intestinal bleeding, seven of gastric hemorrhage, two of bleeding from the kidney, two of hemorrhage from the bladder, and one of hemorrhage due to perforation of an aneurysm. The results on the whole are favorable, though it is hard to estimate just how much of the credit belongs to this particular measure, since other hemostatics were also employed. Well-marked and often very unpleasant by-effects were produced in nearly all instances and make the treatment one not to be advised except in severe cases. Usually pain of varying severity at the site of injection was complained of and lasted for from a few hours to several days. A moderate rise of temperature was frequently noted and in some instances was even accompanied by slight chills. Urticaria-like rashes occurred in a few cases, and once the injections were followed by a deep seated circumscribed swelling in the tissues. It therefore seems that the use of gelatin in this way may be said to promise well for selected cases, though it is likely to be accompanied by unpleasant by-effects, which are not of sufficient severity, however, to contraindicate the measure. It should be tried in all severe internal hemorrhages, and as the effect is only temporary, its application is to be continued beyond the period of acute bleeding. By itself it is often not enough to check the hemorrhage, but other direct or indirect hemostatics should be tried in addition.

Münchener medicinische Wochenschrift, August 13, 1901.

Ileus and Atropine.—Aronheim's patient was a man of fifty-one who suddenly over night developed intense pain in the left hypogastrium. In the succeeding days symptoms of intestinal obstruction developed and did not yield to the usual measures; accordingly one-twentieth grain of atropine sulphate was given subcutaneously to the left of the umbilicus. One hour later there was much less pain, and general subjective improvement; before the next visit the patient passed an enormous amount of semi-solid extremely fetid fecal matter, after which he made an uninterrupted recovery. The only symptoms of poisoning were dryness of the throat and dilatation of one pupil.

The Use of the Stomach Tube in Gastric Ulcer.—W. Flade says that the introduction of the stomach tube in gastric ulcer is by no means a safe procedure and that even though abundant hemorrhage is but rarely produced in this way, still the temporarily slight, but in the long run exhausting, bleeding that may be caused from large ulcerating surfaces is a possibility not to be overlooked. The risk of producing a perforation when the ulcers are situated on the anterior wall, under which conditions the symptoms are likely to be inconclusive and an examination of the gastric contents desirable, is exceedingly great. On the whole, the author assumes rather a negative attitude toward the use of the instrument and says that it may be dispensed with for most therapeutic purposes while its diagnostic uses are too slight to compensate for the risks it entails.

A Case of Intestinal Obstruction Caused by a Gall Stone, Successfully Treated with Atropine.—F. H. Pritchard describes the case of a man of sixty-two years who two years previously had suffered from a severe attack of hepatic colic. Since then he had been fairly well until he came under observation with symptoms which gradually deepened into the typical picture of intestinal occlusion. Hot applications and enemata were unavailing, when one-thirty-third grain of atropine was given hypodermically in two doses within four hours of each other. Five ounces of olive oil were taken by the mouth and an enema was given which, however, came away some time later without fecal result. A few hours afterward several movements took place, at first firm in consistency, later on liquid and containing oil, and finally a gall stone one inch long, three-quarters inch thick, and not quite so broad, was passed. The author ascribes the effect wholly to the atropine and oil and also states that for years he has found that the local injection of a mixture of morphine and atropine greatly facilitates the reduction of incarcerated inguinal and scrotal hernias.

The Atropine Treatment of Intestinal Obstruction.—H. Gebele reviews the experiences of those who have already reported on this method of treatment, and draws conclusions that are not very favorable. Cases of this sort must be divided into two classes, the dynamic and the mechanical, and of these it is particularly the former that are suitable for internal medication. Opium, which has long been in use, is open to the objection of causing gastro-intestinal derangement and opposing subsequent enemata or laxatives, while atropine in the doses that have been recommended produces undesirable toxic symptoms. Both of these drugs are unsatisfactory because they obscure the clinical picture and morphine is to be preferred to either. In the mechanical form of obstruction, internal medication is wholly out of place, and atropine treatment, while it may cause temporary apparent improvement in most instances, simply disguises the patient's real condition and puts off till too late what might otherwise have been a life-saving operation. In short, the author's opinion is that when internal remedies are indicated in intestinal obstruction, *i. e.* the paralytic form, morphine is preferable to atropine, while in true anatomically mechanical ileus only surgical intervention deserves consideration.

Deutsche medicinische Wochenschrift, August 15, 1901.

The Diagnosis of Pharyngo-œsophageal Diverticula.—H. Schmilinsky gives the histories of two patients in whom the diagnosis of œsophageal diverticulum was in the one case corroborated by the autopsy and in the other made more than probable by the *x*-ray examination. The characteristic points in the history of such cases are the dysphagia which frequently, contrary to what obtains in stenosis, is greater for liquids than for solids and the regurgitation of food and mucus. The ordinary œsophageal bougie is arrested at a variable distance from the mouth, while a specially constructed instrument with a curved tip or a second bougie introduced while the first is in place and occluding the entrance to the sacculation, can be made to enter the stomach. By giving the patient bismuth capsules to swallow while under *x*-ray observation, the location and limits of the diverticulum may accurately be ascertained.

The Diagnosis of Deeply Seated Œsophageal Diverticula—W. Zweig describes a simple expedient by which the differentiation between idiopathic dilatation and deep-seated diverticulum may with certainty be made. The capacity of the diverticulum is estimated by noting the amount of fluid that is usually obtained through the stomach-tube passed into it, and this quantity of a dilute methylene-blue solution is then poured into it through a tube which is allowed to remain in place. A second tube is passed into the stomach and then slowly withdrawn. If the methylene-blue solution is contained simply in a dilatation of the œsophagus, it will be possible to siphon off some of this fluid as the second tube passes through it and its end will be stained blue, while if, on the other hand, the fluid is in a true diverticulum this will not occur. The author was able in this way to diagnosticate three cases whose histories he gives as well as that of an instance of simple dilatation, and concludes that as he discovered these three cases in so short a length of time, by the use of more careful methods of diagnosis we may find that the affection is not nearly so rare as has heretofore been supposed.

The Pathological Anatomy and Histology of Carcinoma—Hansemann says that the conception of carcinoma has changed since Virchow defined it as an alveolar heteroplastic growth. Later observers demonstrated the origin of carcinoma from epithelium and of sarcoma from connective tissue and founded their teaching on a histogenetic basis. This standpoint also is open to objection and is complicated by the existence of the malignant endothelion a which at times is carcinomatous and at times is sarcomatous in nature. The author advocates a partial return to the morphological nomenclature and would incorporate in the name of each growth sufficient epithets to indicate what is known concerning its histogenesis and etiology, for example "carcinoma epidermoidale traumaticum" or "carcinoma ventriculi ex ulceratione." Sarcomata normally possess a parenchyma and a stroma, even though the latter frequently consists wholly of vessels and their origin is easy to trace back to the bony, cartilaginous, etc., structures from which they sprang. The cells that compose a malignant growth have two special characteristics, viz.: they are less differentiated than the mother cells and they have

acquired to a greater degree the power of independent existence. This change is to be called anaplasia, an expression which has a purely relative value and can be applied only in comparison with the original cells

French Journals.

Primary Actinomycosis of the Skin.—Thevenot has had a case of this kind, the patient being a merchant aged fifty-three years. The disease began fifteen years before the patient came under observation, in the lobule of the ear. The affection gradually spread over the cheek. The condition has been improved by the administration of iodide of potassium.—*Lyon Médical*, August 4, 1901.

Encapsulated Cavernous Angioma of the Orbit.—Felix Lagrange describes this case. The tumor was congenital. After its extirpation, microscopical examination demonstrated two facts: The presence of a fibrous capsule around the neoplasm; in the neoplasm, pockets containing blood—these pockets were of all sizes and forms. The capsule was in contact with the adipose tissue of the orbit. It was of an irregular thickness, and was composed of several superimposed layers. The walls of the alveoli were very elastic, and their contents were composed of pure blood.—*Journal de Médecine de Bordeaux*, August 4, 1901.

Treatment of Exophthalmic Goitre by Electricity.—Denis Courtade, in describing this treatment, states that it ought to be continued a long time, at least for three months, every day or every two days. At first the palpitations, the tremor, and the general nervous phenomena diminish. The exophthalmos decreases less rapidly. As to the goitre, it diminishes at first very rapidly, then remains stationary; it is sometimes a long time in disappearing. The treatment by electricity should be accompanied by a general treatment of repose, hydrotherapy, and cacodylate of sodium.—*Journal des Praticiens*, August 10, 1901.

Cyst of the Pancreas.—Jaboulay reports a case of this kind in a young man of sixteen years. This tumor seemed to have begun three months previously by colic and vomiting, while at the same time the skin became slightly jaundiced. The swelling had been noticed for a few days only. On puncture, the cyst was emptied of its contents—from two to three litres of brown liquid. The wound was not entirely closed, and rubber drain being inserted. Histologically, the cyst wall was not unlike that of an ovarian cyst. As to the contents, they included the three digestive ferments for starch, fat, and sugar. The general condition was much improved by the operation, although a fistula remained.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, August 8, 1901.

Tuberculous Rheumatism.—Raymond Bernard reports this interesting case of a man of thirty years without tuberculous or rheumatic antecedents. At the beginning of the last winter he began to lose weight; he was very weak and suffered from pains in his heels and toes. These pains, very acute on awaking, would disappear after exercise, only to return after one or two hours of repose. Later, the patient suffered from pain in the shoulders and hands. Several articulations of the fingers as well as of the legs became swollen. The pain was clearly muscular and periosteal. Later, the knees became painful. Salicylates had no effect. The affection, which had been apyretic in the beginning, now became febrile, and the temperature remained above normal for four months. There was another feature to be noted—the persistence of pain in certain muscles for a time, and then its sudden shifting. At the end of February there was no other sign of tuberculosis than the bilateral cervical adenopathy, and in the middle and lower part of the left lung a slightly roughened respiration, with sometimes a few very fine subcrepitant râles. The patient is now much improved; there is no pain, and the fever has disappeared. There remain the characteristic cervical adenopathy, the deformity of the joints of the fingers (proved by a radiograph to be due to periarthritis), and a tuberculous lesion of the lungs. Bacteriological examination from time to time was negative.—*Lyon Médical*, July 21, 1901.

Chronic Gastritis.—Albert Robin concludes his paper on this subject by discussing the course, prognosis, and diagnosis of this affection. The course and prognosis are dependent upon the hygienic conditions in which the patients are placed, upon the manner in which the stomach empties itself, and upon the action of the intestines. When all of these conditions are favorable, chronic gastritis is compatible with a relative degree of health. Although the writer states that he does not know that these patients are ever completely cured, still they may live many years. The prognosis becomes grave with the presence of frequent vomiting, hæmatemesis, and other signs of ulceration. Chronic gastritis should be differentiated from simple ulcer of the stomach, cancer, and gastric neurasthenia. In simple ulcer, pain on taking food, gastric crises, and especially the chemical examination of the stomach contents afford the differential points. When the essential signs of cancer are present—hæmatemesis, coffee-ground vomiting, the characteristic cachexia, phleginasia alba dolens, etc., the diagnosis is not difficult. When these fail, the diagnosis sometimes is a delicate one to make. In gastric neurasthenia, the predominance of nervous symptoms and reflex retention assist greatly in making the diagnosis. The diagnosis of those conditions which have favored the development of chronic gastritis should be studied in minutest detail. —*Bulletin Général de Thérapeutique*, July 30, 1901.

Revue de Chirurgie, July 10, 1901.

Troubles Caused by Wisdom Teeth.—M. Moty says that, leaving out of account the slight irritation of the gum caused by the irruption of a wisdom tooth, there may be graver troubles due to (*a*) proliferation of epithelial débris included within the dental follicle; (*b*) total inclusion of the tooth; (*c*) caries of the tooth. The inflammatory process excited by these conditions is what lends gravity to the situation. The rational treatment consists in extraction of the tooth. Should there be special reasons for endeavoring to preserve the tooth, conservative treatment may be tried, and should consist in curetting the fungosities at the root through an opening in the external surface of the maxillary bone.

Trephining for Old Traumatisms of the Cranium.—Maurice Péraire reports two cases in which the wounds were of seven and twelve years' standing, respectively. In the first case the falling of heavy wood on the head caused in time persistent headache, fever, insomnia, loss of memory, unfitness for work, nausea, vomiting, and weakness of the legs. Trephining revealed an abscess of the brain, and evacuation of the pus caused relief of the symptoms. The second case was one in which a bullet had been imbedded in the brain for twelve years. Of late the patient had been troubled with severe pains of a dull character in the head. The bullet was located by means of the *x*-rays, trephining was performed, and the bullet was removed. Complete relief followed.

Perforating Wounds of the Abdomen.—Eugène Vincent considers that, although it is not possible to lay down fixed rules in clinical surgery, it is probable that there are some conditions under which a certain line of treatment is the best. *In wounds by fire-arms*, it is advisable not to intervene hastily, because the lesions are of uncertain situation, and may be too numerous to be sutured, and because the formation of peritoneal adhesions may prevent the escape of intestinal fluids. In *contusions from a horse's kick*, laparotomy is usually indicated, as we may usually reach the source of the hemorrhage. In *perforating wounds from spear or pike* expectant treatment is advisable, for the intestines have a way of escaping the blunt or sharp ends of weapons. *Wounds from cutting weapons*, knife, sword, bayonet, etc., call for expectant treatment with every preparation for prompt intervention. Laparotomy is obligatory whenever shock, collapse, or the situation of the wound lead one to suspect grave internal hemorrhage, or when there is a localized peritonitis, with some hope of evacuating a collection of pus.

Revue de Médecine, July 10, 1901.

Acroparæsthesia, Tetany, and Gouty Swelling.—E. Brissaud and P. Londe report the case of a man who was unmistakably gouty and neuropathic, and who suffered from periodical symptoms of the extremities, especially the upper ones, which consisted of paræsthesia followed by pain and contracture, impotence of the hands, vasomotor troubles, vaso-dilatation, vascular erythema, and œdema. The writer believes the condition to be of gouty origin. Treatment consists of the use of alkaline waers, colchicum, hydrotherapy, and local hot moist applications. During the paroxysms enemas of chloral and of potassium bromide may calm the pain.

Experimental and Clinical Investigations in Regard to Intrapleural Pressure in Pneumothorax.—L. Bard concludes that the measuring of the pressure of intrapleural gases is an essential factor in the diagnosis of the several varieties of pneumothorax, and chiefly for the recognition of the persistence or the obliteration of a pulmonary fistula. As the estimation of the medium pressure and its character does not furnish exact indications for this diagnosis, we must substitute an estimation of the extremes of pressure. Pressure is positive in both inspiration and expiration in generalized pneumothorax with persistent fistula; it is positive with expiration and negative with inspiration in partial pneumothorax with open fistula; negative in both in generalized pneumothorax when there is no fistula or when it has become obliterated.

Book Reviews.

PRACTICAL SURGERY FOR THE GENERAL PRACTITIONER. By NICHOLAS SENN, M.D., LL.D., Professor of Surgery, Rush Medical College, University of Chicago: Attending Surgeon to the Presbyterian Hospital, etc., etc. With 650 illustrations, many of them in colors. Philadelphia and London: W. B. Saunders & Co., 1901.

THE preface and title page of this large volume state that it is the author's aim and desire to present a work of practical value, chiefly suitable to the needs of the general practitioner. No attempt has been made to cover the whole field of surgery, but certain portions of that field have been very thoroughly worked over—those portions about which, in the author's opinion, the ordinary physician should be best informed. There are preliminary chapters on emergency surgery and shock, both of interest, and a well-written chapter on anæsthetics and their use. The author believes that ether is safer in untrained hands than chloroform, and that ether cones should not be made of impermeable material, with both of which conclusions we agree thoroughly. The control of hemorrhage is described by every method from simple pressure up to ligation of the artery in its continuity, and arterial suture is also discussed, though this procedure will rarely be attempted by any one not a surgical expert. The immediate treatment of traumatism receives the attention which so important a subject deserves, and all the local antiseptics are mentioned and described, attention being directed to their advantages and disadvantages. We are rightly warned not to place too much reliance on chemical antiseptics until our wounded surface has received proper preparation by preliminary scrubbing and cleansing. The subject of gunshot wounds is discussed in the light of recent experience with high-velocity small-bore projectiles, and a number of cases coming under the author's observation during the recent war are detailed. The use of the *x*-ray in this connection is described and illustrated. There are also, in connection with the subject of military surgery, descriptions of methods of transporting wounded and a discussion of what the so-called "First Aid" packet should contain. In the treatment of penetrating bullet wounds of the abdomen, the author is accustomed to place great reliance on the hydrogen test of which he is the originator. Detailed descriptions of the more ordinary forms of fracture are given, but there is necessarily less information than in books specially devoted to the subject. Colle's fracture receives full attention. The question of bone suture and union by operation when nature fails occupies a number of pages which contain much recent information and numerous illustrations.

In the discussion of dislocations, the elbow and shoulder naturally occupy most space. The important subject of peritonitis is begun by a pathological discussion as to varieties and nature, and later symptoms and treatment are taken up. The author warns us against the dangers of eventration in operating on inflammatory conditions in the abdomen, and quotes the opinions of numerous writers on this subject, as well as on other aspects of the same conditions.

Appendicitis naturally receives full discussion, as is also true of intestinal obstruction and the operations upon the intestine. Amputations in general and their indications occupy the last chapters in the book. The author has limited himself to a few methods and has used most of his space on indications. The volume is bound to be a useful work of reference, but would have been more satisfactory in two volumes.

CURABILITY OF TUMORS BY MEDICINES. By J. COMPTON BURNETT, M.D. Second Edition, Revised. Philadelphia: Boericke & Tafel, 1901.

THE principles enunciated in this volume are not likely to find many adherents at the present time, nor would the author's statements on pathological matters remain unchallenged did it seem expedient to discuss them. We may take it for an assured fact that no internal medication has any effect upon an already existing carcinoma in the human body, and as this volume maintains the contrary, nothing further need be said.

SELECT METHODS IN FOOD ANALYSIS. By HENRY LEFFMANN, A.M., M.D., Professor of Chemistry and Toxicology in the Woman's Medical College of Pennsylvania, etc., and WILLIAM BEAM, A.M., M.D., formerly Chief Chemist of the B. and O. Railroad. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1901.

THIS volume is one of convenient size upon a very extensive subject. The authors have aimed at conciseness, and have succeeded in making an excellent laboratory guide, which must prove useful to those who are working in the field of food analysis and hygiene. It is also a book which the practitioner will find useful to have when he is suddenly called upon to examine a specimen of food or drink. The various articles of food and drink are discussed systematically, and we are told what they should and should not contain, and how to discover the ingredients, especially the adulterants. The book contains considerable useful statistical matter.

ORAL SURGERY, A Text-book on General Medicine and Surgery as Applied to Dentistry. By STEWART LE ROY MCCURDY, A.M., M.D., Professor of Anatomy and Surgery, Pittsburg Dental College, etc. Pittsburg: The Calumet Publishing Company, 1901.

THIS is a handbook for the use of dentists and students of dentistry, upon the surgical and prosthetic problems presented by the various pathological processes in the mouth and jaws. The book is systematic and satisfactory.

PRACTICAL URANALYSIS AND URINARY DIAGNOSIS. A Manual for the Use of Physicians, Surgeons, and Students. By CHARLES W. PURDY, LL.D., M.D. Fifth revised and enlarged edition. With numerous illustrations, including photo-engravings and colored plates. Philadelphia, New York, and Chicago: F. A. Davis Co., 1900.

THE worth of this practical guide to urinary analysis has been appreciated. Despite the brief time between editions a rather careful revision has been made, and one new chapter on the use of the microscope in uranalysis has been added. This is a subject on which there has been an appreciable scantiness of adequate information, especially for the beginner. It seems to be an addition well worth the trouble.

COMUNICACIÓN SOBRE SERUM ESPECÍFICO. Por el Dr. EDUARDO MOORE. Santiago de Chile, 1901.

THIS is a reprint on the treatment of syphilis by a specific serum, from a paper presented by Dr. Moore at the first Latin-American Congress.

LA TUBERCULOSE ET LA MÉDICATION CRÉOSOTÉE. Par le Dr. SAMUEL BERNHEIM. Paris: A. Moloine, 1901.

ALTHOUGH many monographs have appeared upon creosote in phthisis, no work that we have seen has laid down the precise indications and has gone so scientifically into the whole matter as has the one before us. The conclusion of the author is that phospho-creosotic medication is called for.

CANCER OF THE STOMACH; a Clinical Study. By WILLIAM OSLER, M.D., and THOMAS MCCRAE, M.D. Philadelphia: P. Blakiston's Son & Co., 1900.

THE chapters are upon general etiology, cancer in the young, symptoms, primary, associated, and secondary, study of the tumor, the blood, course, latent cancer, pathology, and treatment. In 154 octavo pages the writers have presented a serious clinical study of the question which should interest all internal therapeutists.

PHOTOGRAPHIC ATLAS OF DISEASES OF THE SKIN. By GEORGE HENRY FOX, A.M., M.D. Philadelphia: J. B. Lippincott Company, 1901.

THE first part of this new and attractive atlas in colors has made its appearance. The pictures are of acne vulgaris, eczema erythematosum, syphiloderma erythematosum, zoster pectoralis, and dermatitis venenata. There will be eighty plates, illustrating over a hundred diseases. The text, which deals largely with cutaneous therapeutics, is well prepared, and the presswork is attractive. The pictures are evidently reductions from the large extensive hand-painted series recently put out. With the exception of the "erythematous syphiloderm," which gives the impression of a pigmentary eruption, the plates are excellent.

A SYSTEM OF PRACTICAL THERAPEUTICS. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Second edition, revised and largely rewritten. Vol. III. Philadelphia and New York: Lea Brothers & Co., 1901.

THIS volume, containing chapters on anæsthesia and surgical technique, fractures and dislocations, minor surgery, surgery of the lungs and pleura and of the peritoneal cavity, the rectum and anus, diseases of the genito-urinary apparatus and of parturition and of the puerperium, diseases of the eye, ear, and upper respiratory tract—all written by men of prominence in their special line of work—is well illustrated. Especial attention should be called to the progressive steps in operation for appendicitis as depicted in a series of fifteen plates illustrating article on peritonitis, etc. Plate V shows a Venus-like maiden with a lascivious turn to the lip, an ecstatic stare to the eye, and a line upon the abdomen corresponding to that of the oblique incision upon the outer edge of the rectus. There is so much form shown for so small a line that one wonders if Mr. Comstock might not criticise the lack of proportion from an artistic standpoint. However, the other pictures are free from suggestions other than those of how best to carry out the various procedures recommended. The last compares well with the first volume, which was recently reviewed.

Clinical Department.

AN AUTHENTIC CASE OF INJURY BY A SHARK.

By MIDDLETON STUART ELLIOTT, M.D.,
PASSED ASSISTANT SURGEON, U. S. NAVY.

S. M., QUARTERMASTER, third class, U. S. Navy, while in bathing in the harbor of Iloilo, Island of Panay, was attacked by a shark, and his left leg was torn away at the knee-joint.

On June 24, 1901, the patient went ashore with the firing-party, and, as usual, went in swimming about three P. M. with a number of other men. While about thirty feet from the shore in a depth of water of some ten or twelve feet, he was heard to cry out and was seen to disappear for a few seconds. When he arose to the surface he swam toward the dinghy which was ten feet away and was hauled into the boat by his shipmates. It was then seen that his left leg was gone. An improvised tourniquet of a silver match-box and handkerchief was applied, which controlled the hemorrhage. The boat was then started back to the ship, which was one mile away.

On his arrival at the ship it was considered necessary to perform an amputation, which was done by Assistant Surgeon Jacob Stepp, U. S. Navy, I being ashore at the time. After the operation, the patient was in a precarious condition, but rallied well and, on the 26th, was transferred to the U. S. Military Hospital at Iloilo, where he is now progressing very favorably.

The injury was of a peculiar character. The leg was evidently seized about four inches above the knee-joint, the soft tissues bitten down to the bone and torn away at the joint. The edges of the wound were jagged, showing fairly well the shape of the shark's teeth. The lower third of the femur was entirely exposed, as clean as if the flesh had been dissected away.

The accident was witnessed by several men and although no shark was seen there can be no doubt that the injury was inflicted by a shark, for the following reasons: After being drawn under and coming to the surface, the man cried out "shark! shark!" He states now that he has not a clear recollection of what occurred; that he felt a sudden pain in his leg and was drawn down. On his left thumb and index finger were two small triangular-shaped wounds, just the shape that the points of a shark's teeth would make. He evidently, on being seized, thrust his hands down in his efforts to free himself and caught his fingers on the shark's teeth. Sharks have been seen in the same locality by the natives, and one of the latter stated that a native was caught there, three months before. There are no other fish in these waters that could inflict such an injury except a shark.

After the accident, efforts were made to catch the shark, but they were not successful.

ILOILO, P. I., U. S. S. *Annapolis*.

SUCCESSFUL VACCINATION IN CENTRAL AMERICA.

By J. HOBART EGBERT, M.D., PH.D.
SAN JUANCITO, HONDURAS, C.A.
SURGEON TO THE NEW YORK AND HONDURAS ROSARIO MINING COMPANY.

By reason of the distance from the biological laboratories of Europe and the United States, together with the rapidity with which serums deteriorate in a tropical climate, much difficulty has heretofore been experienced in making successful vaccinations in the interior of Central America. Although many attempts have been made to vaccinate the inhabitants of this portion of Honduras, they have always resulted in a very small proportion of "takes."

During the past six months smallpox has occasionally been reported epidemic in this section of Honduras (District of Tegucigalpa), and, although no real evidence of an outbreak of the disease has come to my notice—the alarm really originating in the existence of considerable varicella, which, naturally, among a people of uncleanly habits, frequently made a very ominous showing—I nevertheless decided to demonstrate the facility with which successful vaccination could be made.

In the latter part of the month of March, the company's superintendent, while in New York City, procured from the New York Board of Health fifty tubes of freshly prepared vaccine lymph and brought them without delay to San Juancito. Two dozen inoculations with this lymph resulted in twenty-three excellent "takes," thereby demonstrating its activity and purity. I then undertook the preparation of fresh virus—inoculating healthy selected heifers. These animals, handled according to approved methods, have yielded an abundance of most excellent virus, and the successful vaccination of the rising generation of this community has already been accomplished.

I desire herewith to thank the New York Board of Health for their courtesy in this matter, and I believe it will be gratifying to the Board to know that their product has aided us so much here in tropical America.

EXTRA-UTERINE PREGNANCY.

By H. JANSS, M.D.,
MARSHALLTOWN, IOWA.

THE following case of extra-uterine pregnancy at full term, which was operated on in a private house in this city about seven or eight weeks after the death of the fœtus, seems to me of sufficient interest to warrant publication. The woman was a Bohemian, about twenty-eight years of age, this being her first pregnancy. During her period of gestation she had several severe attacks of colicky pains which would generally confine her to bed for several days. She had quite a severe attack while on a visit in Chicago and another one while on a visit in Elgin, Ill., but although she had had four different physicians, no diagnosis of her condition was made. One day she told me about her case, having calculated that she would be confined in two weeks from that time, and she wanted me to attend her. About the time she was at full term she had a slight flow, but no other indication of a labor and no labor pains such as some authors describe at this time in these cases. From the time of this slight flow she noticed no more movements of the fœtus, and she was fully convinced that it was dead. She, however, improved in health, and as she felt well she did not consult me for nearly six weeks. I naturally wondered why the confinement in this case did not occur. Finally, I met her one day and she told me of her troubles and that she had noticed no more life of the child since the flow. As it was within two weeks of her tenth month of pregnancy according to her calculations, I advised her to wait until that time, which brought it to March 2d. In case labor did not occur spontaneously at that time, I told her I would bring it on. On examination, however, I found the uterus empty and was then convinced that I had a case of extra-uterine pregnancy to deal with. Both the woman and her husband were very anxious to have the fœtus removed, and on March 23d I operated upon her at her own house. Her temperature on the evening after the operation was 99.6°. She made an uneventful recovery.

SIMPLE FORWARD DISLOCATION OF THE SEMILUNAR BONE.

By CLINTON H. CATHERWOOD, M.D.,

NEW YORK.

THE accompanying pictures are so plain that it seems almost superfluous to add anything, yet the case is rare enough to go on record, and no doubt will be of interest.

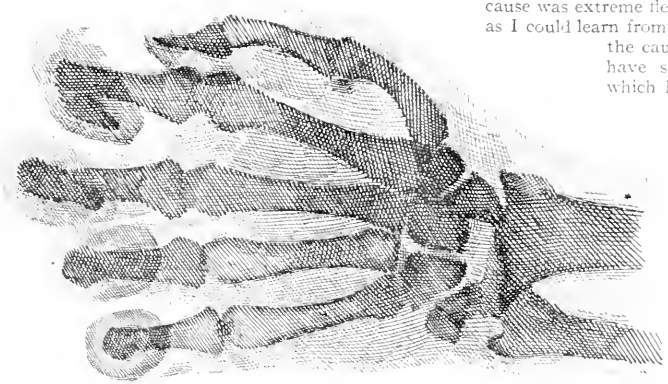

FIG. 1.

The patient, a man of forty-eight, came into my clinic a few days ago with the following history: The night before he lost his balance or tripped while coming down stairs, and pitched headlong. He naturally put out his hands to save himself, and evidently received the greater part of the force on this hand, while in the over-extended position.

When he was first seen, shortly after receipt of injury, the diagnosis of Colles' fracture was made, and this was in a measure correct, as the picture shows that quite a large piece of the lower end of the radius was broken off. The man would allow little or no manipulation, so a temporary splint was applied, and he was told to come back to see me the next day.

I found his hand in about the position shown in these two pictures, that is, the fingers were considerably flexed, and practically fixed in that position; all over the radial side of the wrist joint there was much tenderness, and loss of function of the hand was almost complete.

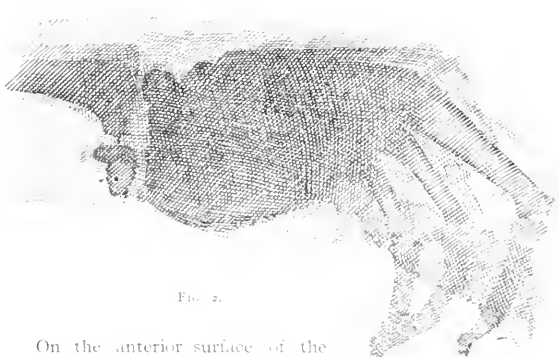

FIG. 2.

On the anterior surface of the radiocarpal articulation I could make out a large but well-fixed piece of bone, which I could not account for as coming from either radius or ulna; on the dorsum of the wrist, just over the place where the semilunar bone should be, I thought I could make out a distinct depression. With these points I was pretty sure I had a dislocation of the semilunar bone, which the *x*-ray picture shows well.

I report this case, as it is extremely rare. Stimson in the last edition of his book, gives the number of recorded cases as thirteen. In seven of the cases the dislocation was compound. Stimson thinks that the cause was extreme flexion in most of the cases; as far as I could learn from this man, the exact reverse was the cause of this particular injury. I have seen one such case before, in which Dr. Stimson removed the bone, and with that end in view I had the man admitted to hospital. He, however, flatly refused all surgical interference, and I shall be much interested to know how he will ultimately come out, as I should think the prognosis rather poor unless something is done to relieve the very much stretched flexor tendons.

55 WEST FIFTY-EIGHTH STREET.

A LIGATURE OPERATION FOR THE REMOVAL OF HEMORRHOIDS.

By FREDERIC GRIFFITH, M.D.,

NEW YORK,

SURGEON, BELLEVUE DISPENSARY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

THE chief danger after ligation for the removal of hemorrhoids is from slipping of the ligature and it is my purpose in this article to describe a method whereby in selected cases, under cocaine anæsthesia, hemorrhoids may be removed without fear of secondary hemorrhage.

Internal or bleeding piles have been divided into the groups of venous, columnar, and nævoid, and it is to the first two forms that the procedure applies. There is, however, a limit to this application, depending on the control of the patient by the operator under the weak solutions of cocaine which are necessitated by the nature of the work. The ease of approach to the hemorroidal masses must be also considered, as full dilatation of the sphincter under cocaine anæsthesia is usually a tedious manœuver both to the patient and the surgeon, and demands special skill for its successful accomplishment. A general anæsthetic will best serve in those cases in which the hemorrhoids cannot be readily reached.

The patient is prepared for operation by a full dose of castor oil given the night before, and a hot water enema as a preliminary step, to clear out the rectum and bring down the hemorrhoids.

The pile to be removed being grasped by the fingers of one hand, a few drops of a one-half of one per cent. solution of cocaine are injected directly under the mucous layer at its apex, or at that portion of the mass where the entrance of a single vulsellum forceps can be best effected. Drawing down on the pile we search for the vein which supplies it, finding it usually coming down from above as a purple line.

With a curved needle a ligature of medium-sized catgut is passed under the vessel after the injection of a drop or two of the weak solution of cocaine to render its passage painless. The ligature is drawn tight and tied with a square knot, and the ends are cut.

The hemorrhoidal mass is next to be removed. After the injection of the cocaine solution in a line around the circumference a little above the base, with curved blunt-pointed scissors the hemorrhoid is dissected out, leaving a somewhat crater-like surface, which is drawn together by continuous or interrupted sutures. The former are to be used if all oozing has stopped; if it has not, by all means the lowest suture to be loose when interrupted sutures are employed, we obtain sufficient drainage and prevent distention of the cellular tissue about the wound. Oftentimes very little of the mucous membrane need be sacrificed, and by the exercise of a little judgment we can prevent undue contraction of the cicatrix.

The after-treatment consists in keeping the bowels loose, and I find that a more rapid healing takes place by having the lower bowel clean (a true physiological rest of the part) than is secured by the five or six days' rest with an impacted rectum when opium is used.

I have employed this operation in three cases. Two were cases of single internal hemorrhoids and uneventful recoveries were made. The third case was in the person of a professional pianist who had been unable to perform for ten days and had not sat down for four days past, on account of inflammation of two hemorrhoids, one internal the other external and internal, from which he suffered. I removed these one afternoon, and he walked away from the office and played all night in a resort. I kept his bowels loose with Epsom salts, and after the first two actions there was no further complaint on his part. The wound healed without further interference.

The advantages of the operation are that it can be done by the operator alone, or at most but one assistant is necessary; also a clean field is obtained (can be secured by the half-dozen hæmostats usually required for each hemorrhoid.

The use of weak solutions of cocaine is a factor in the result. I have employed them at the suggestion of Dr. J. A. Bodine, of the Polyclinic Hospital.

805 MADISON AVENUE.

LOCAL GANGRENE IN ACUTE BROMINE POISONING.

BY C. F. DARNALL, M.D.,

LLANO, TEXAS.

I was recently called to see an opium habitué, a woman, who was suffering from acute pain and smarting in the left thigh, above the knee cap. The lesion I observed was a wheal like that of urticaria, about an inch in diameter. In a short time the spot became vesicular, and the surrounding cellular tissue was swollen and indurated. In a few days over twenty of these spots appeared at different locations on the thigh, and they passed rapidly from the stage of urticaria to gangrene, and the woman suffered a great deal of pain. A few weeks previously I had resolved to try the bromide treatment to cure her of the morphine habit, and gave her a prescription containing two ounces of sodium bromide to six ounces of water, with directions to take it in teaspoonful doses every two hours until she felt the sedative effects of it. We had been trying everything to break her, and she would swallow anything she could get in her hands. When the morphine was cut down she began to use the solution so freely that her husband thought the cure was working all right, and without mentioning it to me, had within six days taken the bottle back twice to the druggist, making six ounces she had taken in that time. Indeed, she had a positive mania for swallowing drugs. While she was under treatment for the gangrene, I left with her husband an ounce bottle of formaldehyde to make a wash for the limb; this she promptly swallowed as soon as she found where it was hidden, but her husband gave her at once hypodermically a dose of apomorphine, which soon emptied her stomach. For two weeks after the first sore appeared she was under the influence of the bromide, was stupid, had scanty urination, no appetite, and her breath was very foul. My treatment was tonic and eliminants, with antiseptic washes. Recovery was very slow, and it was weeks before she could sit up. About the eighth week I removed the first plug of dead tissue, and every one of the places had to be cut out with scissors. There were but slight constitutional effects aside from those I have mentioned, and we had to continue the use of morphine until she was well of the gangrene. Since that time she fortunately has quit the use of morphine, and is well. Where the limb was ulcerated deep scars remain, but there is no lameness.

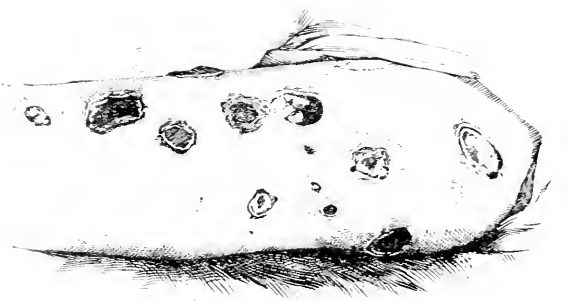

FIG. 1.—Local Gangrene of the Left Thigh in Acute Bromine Poisoning.

Physiological Effects of Radium Rays.—All the leading workers on the subject of radium rays have in turn subjected their own persons to some painful experiments for the advancement of their fascinating branch of science. Giesel placed a radium preparation in a celluloid case on his arm for two hours. The skin only showed a slight reddening at first, but, two or three weeks afterward, inflammation set in, and the skin came off. P. Curie was the next voluntary victim. He exposed his arm to the Becquerel rays. On the twentieth day a crust formed, and then a sore, which had to be bandaged. On the forty-second day, the skin began to reform, but even on the fifty-second day after the exposure a grayish tract of skin remains to indicate the mortification. H. Becquerel placed a very active radium preparation in his waistcoat pocket for six hours. The resulting sore, which took ten days to develop, required thirty-nine days to heal. Another sore took thirty-four days to develop. No action was produced when the tube was inclosed in lead. Madame Curie underwent experiments of a similar nature. The preparation was in her case inclosed in a thin metallic box and only applied for half an hour, but the resulting burn took two weeks to heal. All those who worked with the very active preparations experienced pains and sores in their fingers which took two months to get well.—*Scientific American Supplement.*

Therapeutic Hints.

A Mechanical Laxative for Infants.—H. Beer (*Klinisch-therapeutische Wochenschrift*) says that he would recommend his method in preference to the large array of laxatives because (1) all the internal laxatives act more or less chemically and not mechanically; (2) this method is interesting from a physiological standpoint, and (3) under certain conditions it is superior to all others. The method is as follows: The bulbous end of an ordinary rectal thermometer is smeared with vaseline and inserted per rectum as in taking the temperature. It is then gently pressed against the sphincter ani and, keeping it in the axis of the rectum, it is made to describe smaller and larger circles as if dilating the sphincter. After two or three turns the sphincter is felt to relax, the rectum contracts, the anus opens and the act of defecation takes place reflexly. If the defecation is incomplete, the procedure must be again carried out. The effect is very prompt when the rectum is filled and it is absolutely harmless to the child inasmuch as the entire procedure is painless, and its temporary as well as remote effects upon the sphincter and rectum are harmless. It is generally known that when the rectal temperature is taken children often evacuate their bowels, and upon this fact the method was based In many febrile conditions the children are constipated; in these cases a laxative is given per os or the bowels are moved with enemata or suppositories. Laxatives per os often aggravate the existing loss of appetite, produce colic, and instead of causing one evacuation give rise to numerous movements. The latter may cause perianol eczema and affect the general condition by the unnecessary loss of fluid. Filling of the rectum is partly painful Suppositories cause pain. All these inconveniences can be remedied, if, while taking the rectal temperature, the above-mentioned movements are carried out. In temporary constipation occurring in non-febrile affections this method is also advocated. In chronic constipation it stands second to dietetic changes, but is still very useful as a palliative measure.

Antidote for Formaldehyde.—In view of the fact that this chemical is coming more and more into general use as a disinfectant and antiseptic, cases of poisoning from it will become more frequent. We have an easily accessible and reliable antidote in ammonia water. It may be given in the form of ammonia water (a few drops well diluted) or the aromatic spirit or a solution of ammonium acetate.—*Merck's Archives.*

Treatment of Heart Lesions in Infancy and Childhood.—The prophylactic treatment of pericarditis and endocarditis depends upon the fact that the majority of these cases are rheumatic The salicylates should be used thoroughly and early. It is undoubtedly true that the salicylate of sodium does not exert any direct effect on rheumatism of the heart already established, but nevertheless the drug limits the rheumatic process, and may possibly arrest its progress before it has seriously injured the endocardial or pericardial structures. There are those who believe that the administration of salicylates predisposes to cardiac involvement. There is not, however, sufficient evidence in support of this view to make it tenable Alkalies used alone or combined with quinine or salicylates are warmly recommended in some quarters for the treatment of the rheumatic state. Rest in bed should be insisted upon and begun early in the disease. The external application of an ice-bag is advised by many on the principle that cold inhibits cardiac action and exerts a favorable influence on the inflammatory process Some clinicians advocate the use of hot applications, these are particularly indicated for the relief of precordial pain Counter-irritation in the form of mustard paste or the tincture of iodine seems at times to give relief. To quiet the heart, which is laboring as the result of endocardial or pericardial inflammation, small doses of aconite are sometimes employed. If, however, the heart's action is feeble, associated with cold extremities, or if there is the slightest suspicion that the patient is threatened with collapse, if there is cyanosis or dyspnœa, aconite contraindicated. Opium in the form of Dover's powder or small doses of the alkaloids may be employed. When a large pericardial effusion causes interference with the heart's movement, aspiration should be resorted to. The needle is best inserted in the fifth intercostal space a trifle to the left of the sternum. It should be directed upward and toward the axillary line. After the valvular lesion has become chronic the patient should be placed upon a nutritious diet. The patients frequently have no subjective symptoms, and require rest in bed more than anything else. Holt, in a recent paper, emphasizes the importance of rest after acute cardiac inflammations. He believes that dilatation comes on readily and progresses more rapidly than in adults. He would keep his patients in bed after these inflammatory attacks, not for two or three weeks, but for as many months. When the heart begins to dilate and compensation fails, cardiac stimulants are indicated. Digitalis, strophanthus, convallaria, and caffeine are used.—J. A. Abt. *Medicine.*

Variola may be shortened by applying a strong ichthyol ointment. Kamneff.

In Opium Poisoning tickle the patient under the short ribs or under the nose or elsewhere; tickle not to death, but possibly to the point of delivery from it. This is the recommendation though not the phraseology of W. H. Lyne, in the *Virginia Medical Semi-Monthly.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, held Thursday Evening, June 6, 1901.

HERMAN KNAPP, M.D., IN THE CHAIR.

Presentation of a Portrait of Dr. Thomson.—After the reading of the minutes and report of the Committee on Membership Dr. W. H. POLK delivered an address, presenting the portrait of William H. Thomson, M.D., a former president of the Academy.

Dr. Polk said that it gave him great pleasure to present to the Academy through the President the portrait of Dr. Thomson, who had been an honored member of that body since 1864. The fact that Dr. Thomson had been President of the Academy was cause enough for the placing of his portrait among those honored ones now there, but he felt that while Dr. Thomson was well known and associated with the interests of the city, his greatest success had been achieved as a teacher. He had taken the subject of Materia Medica, which had been previously considered the most difficult and uninteresting of all studies, and had brought such skill and power to bear upon it that he had transformed it into one of the most interesting subjects. Dr. Thomson's methods of instruction had been adopted not only in this city but throughout the entire country. Dr. Polk said there was a certain circumstance that acted as a restraint upon his remarks and one was the fact that Dr. Thomson was still alive. None would refrain from saying that he was a peer among peers and when his work was finished and he had passed away many would be the words of high praise spoken of him.

The Freezing-Point of Urine, its Determination and the Inferences Which May be Drawn from it.—DR. J. H. HUDDLESTON read a paper on this subject in which he said the theory of Urinary Cryoscopy is that the determination of the freezing-point of urine determines also the number of molecules of urinary substances dissolved in the water of the urine

All the sodium chloride molecules are excreted through the glomerular epithelium, and part of them are absorbed back into the blood from the tubules. All other molecules are excreted through the tubular epithelium and replace, molecule for molecule, the sodium chloride which is absorbed. If the urine passes rapidly through the tubules there is little time for this exchange, and if on the other hand the passage is slow the rate of interchange is high

The ratio of the temperature of the freezing point, T, expressed in hundreths of a degree centigrade, to the percentage of chloride, Cl, in the urine (T.Cl) expresses the amount of interchange and is the ratio studied. If there is renal stasis or injury to the wall of the glomeruli, as in glomerular nephritis, the rate of urinary flow is slow and the rate of interchange is high Whatever the rate of urinary flow, if the epithelium of the convoluted tubules performs its work badly the rate of interchange is low. The importance of the method, therefore, is its value as a test of renal function, shown especially in its ability to detect the slightest amount of renal hyperæmia.

The freezing point is obtained by a specially constructed thermometer placed in urine contained in a double-walled tube resting in a freezing mixture of ice and salt.

DR. LABOWSKI said it was a question that the surgeon had to face when he came to operate upon the kidney, especially when it was necessary to remove one kidney, whether the other kidney was in a normal condition and would perform the function of excretion so that the patient would not die from anuria as was sometimes the case. The method of drawing the urine from each ureter and analyzing it proved helpful, and now with the aid of this method of determining the functional activity of the kidney, described by Dr Huddleston, the surgeon could feel much safer

DR. ALFRED MEYER said he was not quite so optimistic in regard to the feeling of security the surgeon might have when he combined the two methods of uranalysis, for there often occurred cases in which anuria supervened from what was called sympathy. Cases occurred when there was renal colic and the other kidney failed in its functions entirely, and so the same conditions came on at times in case of operations. While the method described would be of help in determining the blood condition and the condition of the kidney, yet it would not insure against the occurrence of anuria.

The Early Recognition and Management of Arterial Degeneration.—DR. LOUIS FAUGÈRES BISHOP read this paper. The conditions that most occupied the attention of the general practitioner were not those, he said, to which definite names could be given or which could be health reports of a community. Such a condition was figured in the arterial degeneration, which later might be known as Bright's disease, heart disease, paralysis, gout, senility, etc.

A popular belief was that the chief danger of arterial degeneration was rupture of a blood vessel, but that was comparatively one of the least common results of the degeneration Greater dangers were the secondary effect on the heart, kidneys and thrombosis. The form of arterial degeneration that was of the most interest to the general practitioner was that which affected the small arteries and gave the early signs of disordered function. This early tension led to disorder of the heart and kidneys, but there was a stage even preceding that when there was temporary irregular action of the vaso-constrictors, mostly affecting the brain and manifested by temporary loss of consciousness, dizziness, etc. The symptoms of advanced arterial degeneration might be foreshadowed by the functional degenerations of the arteries that foreboded organic disease.

The study was purely a clinical one and in practice it was difficult to say when degeneration had become sufficiently advanced to be demonstrated. The condition was usually found among the most useful class in the community, young energetic business men who labored under great mental strain.

The degeneration was first fatty, then connective tissue was formed, and then later calcification. Heredity was a powerful factor in its development, and alcoholic poisoning, gout, syphilis, the retention products of Bright's disease, and chronic blood poisoning all played an important part.

The management of arterial degeneration, when the condition was distinctly recognized, must be more hygienic than medicinal. When syphilis prevailed the iodides would be used. When alcohol was a cause its consumption must be limited. Many patients who had formed the habit of drinking would not give it up entirely, so it was well to limit the amount and permit it only with meals. In the early stages of arterial degeneration digitalis and iron were contraindicated, but the use of alkalies, an abundance of water, and bitter tonics proved helpful.

In the type of cases described as chorea of the blood-vessels the bromides were of great value. In the older cases shown by the irregularity of the circulation of the brain, as manifested by slight hemiplegic symptoms, the use of the iodide of sodium in small but persistent doses and the administration of nitroglycerin for part of the time proved of great value. It was important that persons in whom arterial degeneration was developing should adjust their lives so as to avoid heavy responsibility.

Sansom had pointed out the mental symptoms of commencing arterial sclerosis after middle life. He said that such patients became fanciful, introspective, low spirited, and moody, but showed no obvious signs of disease other than those of dyspepsia. Those persons who had the temperament most likely to develop arteriosclerosis were

not likely to consider the matter of much importance, and probably a hemorrhage alone would arouse them to the seriousness of the condition. It was of the most import to watch these cases so that the patient might attain a long life and enjoy health, and success was bound up in the regulation of those conditions that tend to hasten or delay arterial degeneration.

A beginning arteriosclerosis might produce a neurasthenia that checked the tendency to overwork and thus many were saved from arterial degeneration.

Dr. Knapp said the subject presented by Dr. Bishop was one of great importance. He remembered a case he attended twenty-five years ago in which the patient had hemianopsia which was difficult to explain. The autopsy showed that the arteries of the entire circle of Willis were atheromatous and extended so in effect that hemianopsia was the result.

A Hospital for the Treatment of Incipient Tuberculosis.—Drs. A. Jacobi, J. L. Peabody, E. G. Janeway, Alfred Meyer, and A. H. Smith were appointed a committee to take into consideration the question of establishing a hospital for the treatment of incipient tuberculosis.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 8, 1901.

Edward K. Dunham, M.D., President.

Syphilitic Ulcers of the Larynx.—Dr. L. T. Le Wald presented this specimen. The case was interesting on account of the fatal issue. The specimen showed a ragged ulcer measuring 3 by 1 cm. on the anterior aspect of the larynx in the region of the cricoid cartilage. There was considerable infiltration about it. There was a second ulceration measuring 4 by 2 cm. on the lateral aspects of the larynx, about the thyroid cartilage, below the vocal cords. This also presented a ragged, irregular centre and grayish borders. The patient was a woman, thirty-six years of age, who had been brought to Bellevue Hospital suffering from intense dyspnœa. She was unconscious at the time of admission, and a hasty tracheotomy was done through the third ring of the trachea. Death occurred about two hours later. A diagnosis of probably syphilitic ulcers of the larynx had been made by the house-surgeon, although no opportunity had been afforded for a laryngoscopic examination. At the autopsy there was a moderate œdema of the larynx in the region of the arytenoid cartilages, and the heart was dilated and very flabby. Apparently death had resulted chiefly from the dilatation of the heart, the latter having been dependent more upon the prolonged dyspnœa than immediately upon asphyxiation. Sections of the lower ulcer showed a superficial necrosis and a round-cell infiltration in the deep tissues. There was no evidence of tuberculosis here or elsewhere in the body. The lymph nodes generally showed a hyperplasia, apparently of syphilitic nature.

Two Cases of Malignant Gonococcal Endocarditis.—Dr. R. J. Wilson reported these cases, which were chiefly interesting, he said, because of the fact that apparently only three had previously been reported in which the gonococcus had been found in the blood before the death of the patient. Before the recovery of these organisms from the blood there had been no suspicion of the presence of the gonococcus. The cases occurred in the First Medical Division of Bellevue Hospital. The first blood cultures had been made on December 18, 1900, three bouillon cultures being made in tubes containing about 3 c.c. The blood had been taken from a superficial vein on the outer surface of the left wrist. The cultures were incubated at 33° C. and examined at the end of twenty-four hours. At this time there had been no appreciable growth in the broth. At the end of forty-eight hours there was no change in the bouillon, but the plates showed small delicate surface colonies looking to the naked eye like minute drops of serum. As the speaker had no idea of what the colonies were, Loeffler's blood serum was selected as the medium for culture. Of the new cultures, only one had developed organisms, and here the growth was very scanty. New cultures were made in other blood-serum tubes, and from these further experiments were made. The cultures were made in the ordinary nutrient bouillon and on agar, and, with one exception, they failed to develop. A smear made from the original colony gave a diplococcus which stained irregularly with methylene blue. On December 28, or ten days later, he again attempted to make cultures from the blood. One cubic centimeter of blood was obtained, but no organisms could be recovered. The patient died on the following day. The autopsy showed vegetations on the heart valves, and a double pyosalpinx. Sections of the vegetations showed numerous diplococci identical with those found in the blood cultures.

The second case occurred on March 10, 1901, and cultures were made with $1\frac{1}{2}$ c.c. of blood. One-half of the specimens were cultivated anærobically, and the others in the ordinary way. Nothing developed. On March 23, the speaker again made cultures from this case, using glucose agar. This time four colonies developed on one plate, but in transferring them they became contaminated. On April 1, another series of cultures was made. At the end of twenty-four hours' incubation, nothing was visible. At the end of forty-eight hours, one agar plate and one glucose agar plate showed colonies resembling those found in the first case. They were transferred to Loeffler's serum. The urine was then centrifugalized, and in the sediment a diplococcus was found which was apparently identical with that isolated from the blood. He had attempted to cultivate these organisms, and had obtained many organisms, but nothing like a pure culture.

Dr. G. Langmann asked which valves of the heart had been involved in these cases. He knew of two cases of malignant endocarditis reported by Dr. I. Adler, in which the presence of the gonococcus had been proved. In each case the tricuspid valve had been involved, and he was under the impression that Dr. Adler had stated at the time that he had noticed that the gonococcus exhibited a predilection for this valve.

Dr. A. J. Lartigau said that if the reported cases of gonococcus endocarditis were analyzed he thought that the left side of the heart would be found to have been most frequently involved. He had himself analyzed a series of fifteen fairly conclusive cases, and had found that the mitral valve alone had been involved three times, the aortic eight times, and both valves of the left heart two times. The tricuspid was found to have been involved but once and the pulmonary twice.

Dr. F. C. Wood said that in cases due to the pneumococcus the right side of the heart was more commonly affected.

Dr. Charles Norris asked if the first case had presented conclusive proof of its being of gonococcus origin.

Dr. Wilson replied that the organism would not grow on ordinary media, and was identical in its cultural and staining peculiarities with the one isolated in the first case, and which had been controlled by fifteen cases of gonococcus cultures. The proof was not quite conclusive, it was true, but he had had no opportunity of cultivating the organisms from the urine. He believed no bacteriological examination had been made of the double pyosalpinx.

Dr. E. Libman said that if one used the serum-glucose-agar suggested by him, one must be careful before making a positive diagnosis that the colonies observed are those of the gonococcus. For while there is a better chance of obtaining colonies in this medium, some bacteria that are usually not decolorized in the Gram procedure may here become decolorized, probably because of the acid production. Furthermore, the acid production may decrease the vitality of the organism so that it will not grow at all, or at least not on the ordinary media. This is mainly true

if one waits too long before transplanting the colonies Careful attention to the morphology and to the reaction to the Gram stain in media not containing sugars is therefore necessary.

Observations on the Staining of Malarial Organisms.—Dr. F. C. Wood made some remarks on this subject. He referred to the use of the combination of eosin with methylene blue, a stain which would color the chromatin particles in the malarial organism. The process had been variously modified, a recent and most excellent one being that devised by Goldhorn. This stain showed a peculiar granular staining of the red cells, especially of those attacked by the malarial parasite. This, it had been stated, was the so-called granular degeneration of the cytoplasm of the red cell. The speaker, while not wishing to deny that granular degeneration was often present, claimed that the granules seen after Goldhorn's method were often either artefacts due to precipitates formed in the red cells or a special form of granulation described by students of tropical malaria as dotted red cells or "tüpfelig" cells, but were not true granular degeneration.

By the method of Goldhorn a precipitate is formed in the red cell and it is this which gives rise to these small granules. If the specimen were treated for an instant with alcohol, all of these granules could be washed out of the single cells, while they would remain just where two cells overlap because here the alcohol does not penetrate so quickly. He had also found that the granules could be obtained very easily in normal blood They were not especially abundant in the blood of rabbits, in which injections of pyrodin or lead acetate had caused all stages of true granular degeneration.

Dr. James Ewing said that when he had first seen specimens stained by Goldhorn he had assumed that these granules were due to a precipitate. Since that time he had come to the conclusion that the Goldhorn stain brings out the true granular degeneration of the red cells somewhat better than other methods He had found, as Dr. Wood had done, that it was difficult to wash out the granules in cells which overlap, but he had finally decided that these were not artefacts because of their uniform presence in cells infected by parasites, even when fixed by other methods. The mere fact that they disappeared under the action of such a general solvent as alcohol was not a sufficient reason for assuming that they resulted from a precipitate. These particles were not crystalline, but granular. There was certainly great danger of mistaking artefacts in the red cell for true granular degeneration. Many such seemed to be dependent for their formation upon too short a period of fixation.

Dr. Wood replied that the chromatin remained stained for a considerable time after treatment with alcohol, although all of the granules disappeared. The infected red cells stained by Goldhorn's method were practically all granular, which was far from being the case if they were stained by almost any other method intended to bring out this granular degeneration. If the specimen were hardened in alcohol for half an hour or more the granules were not so likely to be present.

Abdominal Aneurism Rupturing into the Right Pleural Cavity.—Dr. Lewis A. Conner presented an abdominal aneurism rupturing into the right pleural cavity. It had been taken from a man, thirty-four years of age, a fisherman, who had given no certain history of syphilis. For five months he had had moderate epigastric pain. On April 26 he had been suddenly seized with severe epigastric pain and syncope, and had been brought in the ambulance to the Hudson Street Hospital. The speaker had seen him within an hour, and had found him in collapse. There was a prominence of the epigastrium and a fairly distinct pulsation. The chest became completely filled with fluid, and on aspiration, twenty-four hours later, this fluid proved to be blood. The epigastric pulsation had now disappeared, and the pain had ceased. The man lived for five days after this attack of pain, and during this time presented very few symptoms except dyspnœa, slight fever, and marked pallor. At the autopsy, it was found that instead of being an aneurism in the lower part of the thorax it was an aneurism of the abdominal aorta. It had formed at a point opposite the cœliac axis, had eroded considerably the first and second lumbar vertebræ, had pushed its way up behind the liver, and had ruptured through the diaphragm. Although four litres of blood were found in the right pleural cavity the man lived for five days after the rupture.

Primary Sarcoma of the Thyroid.—Dr. A. J Lartigau read a paper on this subject. In commenting on the literature he brought out the fact that cases of primary sarcoma of the thyroid were exceedingly rare. He had been able to collect fifty-five cases, including his own. In comparing the frequency of primary sarcoma of this organ with that of secondary disease of the same nature, it was shown that the latter was also infrequent. For the most part, cases of primary sarcoma have occurred in goitrous districts, and the majority of affected individuals have given a history of previous goitre. Dr. Lartigau's case was as follows: The patient was a married woman, forty-five years of age, who had been admitted to the hospital January 3, 1901 She had been in good health before the present trouble, with the exception of previous goitre involving the right lobe, which dated back for a period of eight years. Shortly before admission there suddenly appeared in the region of the mid-clavicle a small nodule which subsequently proved to be a hæmatoma. No enlarged lymph nodes were detected. The main tumor involved the right lobe in the mid-neck, displacing the trachea to the left. The operation for removal of the mass was performed by Dr. Brewer. The patient's condition remained satisfactory for several days, after which time a secondary growth was observed involving the remaining isthmus and left lobe of the thyroid. Ptosis and pupillary inequalities developed, and the patient died, apparently from asphyxiation. The autopsy showed recurrence at the original seat of the tumor, with involvement of the remaining thyroid and perithyroid tissue. The œsophageal and tracheal lumina were much reduced by compression No metastases were observed elsewhere in the body

An analysis of fifty-one cases of primary sarcoma of the thyroid showed that in thirty-five goitre had previously existed. Of eight cases developing between twenty and forty years of age, one-half showed previous goitre; while in a series of thirty-two others in which the sarcoma had developed between forty and sixty years, 84 per cent had had goitre prior to the development of the neoplasm Previous goitre seemed to be more frequent in women. Of the fifty-five cases reported, forty-five developed in persons between the ages of forty and seventy, the greater number between forty and sixty. The influence of sex and of traumatism appeared to be unimportant. In the majority of cases the sarcoma originated in the right lobe of the thyroid. Sarcomata of the thyroid ordinarily progressed quite rapidly, the average duration being about eight months. Death often resulted from involvement of the trachea or œsophagus or both. The mortality after operation for removal was quite high.

The Morphology of the Diphtheria Bacillus.—Dr. Anna Wessels Williams presented a study based upon forty pure cultures, which were isolated from a series of throat cultures, showing in smears, besides the ordinary throat bacteria, suspicious or diphtheria-like bacilli. There were frequently only a few of these bacilli present, and at first it was found difficult to isolate them, both because there were so few and because, as it later developed, those varieties of the diphtheria bacillus which appear oftenest in atypical form do not grow well upon agar when first isolated. It was found, however, that all varieties grow very well in ascitic broth even in the

presence of other bacteria, and generally form a decided pellicle in twenty-four hours. After this fact had been demonstrated, ascitic broth was used in helping to isolate the few atypical bacilli. After making agar plates from such a culture a mixture of the whole culture was put into a tube of ascitic broth. From the pellicle which formed in twenty-four hours new agar plates were stroked. Within twenty-four hours these sometimes contained almost pure cultures of the diphtheria bacillus, and nearly always there were many isolated colonies.

The pure cultures, all of which were virulent, and produced the specific toxin, were studied on seven different culture media; and it was found that in each culture, while there was great variation among the individual bacilli, certain morphological characteristics predominated, and that these remained fairly fixed for a number of culture generations, and also in successive cultures taken from the same case when similar culture media were used and cultures of the same age examined. It was furthermore found that though each culture showed these individual characteristics, yet, when the characteristics of all were compared, two broad groups could be recognized in which those cultures having the distinct characteristics of the one group differed widely from those having the distinct characteristics of the other, while between these extremes there were many gradations in type. The cultures placed at the two extremes differed from each other in the following general particulars: The first four showed most distinctly on two per cent. peptone agar after two days' growth; predominating bacilli in cultures at the one extreme were very large and showed large Indian-clubbed ends and decided branches; they were composed of many segments, contained many metachromatic granules, more or less irregularly placed, and divided according to the position of these granules; they grew moderately slowly and scantily; surface colonies macroscopically were small and delicate and microscopically were small, coarsely granular, and non-spreading, with little or no central heaping; in alkaline two per cent. peptone broth they grew slowly and scantily, generally in tiny grains which formed a more or less dense precipitate, and they produced slight if any cloudiness and no pellicle. On the other hand, characteristic bacilli in cultures of the second group were small, had only occasionally small Indian-clubbed ends, showed fewer and smaller branches, slight, if any, segmentation, and few granules, more or less regularly placed, one at either pole or both, or near the middle of the bacillus or in all three positions; they divided more regularly according to the position of these granules; surface colonies macroscopically were moderately large and thick, and microscopically were large, more finely granular, and spreading with central heaping; in alkaline two per cent. peptone broth they grew rapidly and abundantly, clouding the broth and producing an abundant flaky pellicle and precipitate in twenty-four hours.

A practical application, the author said, might be made of the fact that there is a permanence of the predominating types in each culture from the same case, in helping to trace sources of infection. Another practical point was that when typical bacilli persist in a patient after convalescence from an attack of well-marked and characteristic diphtheria, there is very little need of testing the virulence of such bacilli.

Dr. LARTIGAU asked Dr. Williams whether she had noted any definite relation between the morphological groups and the toxin production.

Dr. Williams said that all of the branched forms tested for toxin production had been found fully virulent. The bacilli which were the most virulent had the largest number of branches and segments.

Dr. E. K. DUNHAM said that he had been struck with the fact that in this ascitic bouillon a medium had been found which seemed to favor greatly the reproduction of the diphtheria bacillus, just as peptone favored the growth of the comma bacillus. Observations on development might, he thought, vary a good deal in their results, depending upon the culture media used.

Medical Items.

Discussion on Alcohol at the Edinburgh Medico-Chirurgical Society.—Professor Sims Woodhead opened the subject, stating that it was advisable to determine whether alcohol was a poison, a drug, or a food, or, if all three, in which capacity it played the most important rôle. Its toxic action he considered granted. As a food, though it is oxidized in the body, it does not supply sufficient calories for the maintenance of body heat; it contains no nitrogenous element, it accelerates tissue waste because of its ready oxidation, requiring more oxygen than is normally furnished by respiration, and interfering with the normal oxidation of carbohydrates and fats. Alcohol is a cumulative poison, and it is well recognized that it predisposes to certain infective diseases; many examples from laboratory observations were cited in support of this. The author further believed that alcohol alters the blood by reducing its alkalinity, diminishing its bactericidal power, and producing some leucopenia, and particularly producing increased susceptibility of the tissues to most infective agents. In this connection many experiments have been made with diphtheria toxin, and it has been shown that the use of alcohol greatly increases the susceptibility to this poison. Alcohol exerts a definite action upon the nerve-cell protoplasm, but more study and experimentation are necessary before this action is well understood. It has been noted that in acute alcohol poisoning there is evidence of marked changes in the thermogenic and thermo-regulatory systems, the temperature in a rabbit being reduced 1.9° C.

Professor T. R. Fraser believed that the therapeutic and social value of alcohol in small quantities should not be overlooked, and that in deciding its relative merits there should be more discrimination in regard to the effect of different quantities. He believed experimental evidence sanctioned the frequent therapeutic use of alcohol as a heart stimulant, not only when the heart is weak, but when there is imperfect blood distribution. In regard to digestion, small quantities of alcohol improve that function, while large quantities paralyze it. Small quantities also further nutrition and supply energy, the food value being equivalent to that of an equal weight of fat, and, while incapable of modifying nitrogenous metabolism, it replaces carbohydrates and economizes fats. Alcohol is clinically an antipyretic. Referring to the remarks of the previous speaker, that there is a certain amount of experimental evidence that alcohol increases the infectivity and virulency of pathogenic organisms, he considered this action comparatively unimportant except in cases of extreme immoderation in the use of alcohol, and cited the low percentage of mortality of Europeans in an epidemic of the plague in India as against the high death rate of the natives, the former all using alcohol to a greater or less extent, while the natives did not use it at all.

Dr. Clouston stated that alcohol was responsible for twenty to twenty-five per cent. of mental diseases, but that, in connection with this fact, must be considered the neuropathic brain on which the alcohol has to work, the inference being that if this did not disturb the mental balance, some other factor would, and also that in many cases the excessive use of alcohol is the symptom rather than the cause. Alcohol had its most potent and temporarily fascinating effects on the most sensitive brains, recognized as belonging to artistic and poetic individuals; while it produced intense enjoyment, it no less exerted destructive influence, but when a reasonable moderation was practised, he considered that the ethical sense of

mankind was not disturbed. Alcohol produced its effect more easily on the subject who had become addicted to its use, some molecular change in the brain cells occurring which rendered them more irritable. He admitted the effect of excessive alcoholism on the higher nervous functions to be terrible, and thought that, considering the prevalence of the neuropathic brain and the ignorant abuse of alcohol, the profession should emphatically express an opinion to the effect that this excessive use of alcohol is one of the most menacing conditions of modern society.

Dr. Affleck gave his opinion that, while he should not like to be without alcohol as a therapeutic agent, he regarded it as an emergency remedy. He considered some of Professor Fraser's statements, particularly those in regard to immunity from plague in those persons who drank alcohol, as open to question. He thought post-mortem observations would bear out his conclusion that the effect of habitual small doses was often disastrous, and while he did not deny that alcohol has its uses, he expressed himself as disappointed in it. He recognized a great sense of responsibility in ordering alcohol for a patient, and was exceedingly careful about so doing. His conclusion was that, unless the practitioner conscientiously believes that alcohol is the one thing necessary in a given case, he should not order it.

Dr. W. Leslie Mackenzie considered alcohol in its relation to public health. Directly, it produces a series of fatal diseases, and increases the susceptibility to many others; indirectly, it lessens the sense of social responsibility in any grade, and impedes the course of social development; but there are doubtless many counteractives at both ends of the social scale, and there is this to be said of the four-ounce-a-day drinker, that he lives in a state of persistent mental erethism, and while the wear and tear of alcohol on his economy is more, the wear and tear from circumstances is less, and some allowance must be made for the habitual inconsequence of such a life. In the relation of alcohol to infection, generally speaking, with a bad alcoholic history, the case mortality in certain infections will be higher; on the other hand, a bad alcoholic history is seldom established till after the age of forty, when the physiological susceptibility to most infections is less. Typhus is more fatal in alcoholics. Facts concerning the prevalence of cholera in various districts, alcoholic and non-alcoholic, justify the discarding of the drug as a predisposing factor, or as seriously influencing the case death rate. The plague cannot be said to be much influenced by alcohol at any stage. Pneumonia would probably do better without alcohol. As to whether alcohol is in some degree indispensable as a food, more proof is necessary before it can be concluded that it satisfies any primary organic appetite. The alcohol question being of much wider scope than its relation to public health, it can be better controlled than by public health organizations, and the solution of the problem, at least as concerns the lower classes, appears to lie in improved environment and the inculcation of better physical and moral habits.

Dr. James Ritchie believed that more attention should be paid to the gathering of facts based on experience with actual cases than to the deductions of laboratories. He cited numerous statistics from insurance companies showing the greater risk in the case of non-abstainers. His own experience led him to conclude that alcohol predisposed to gout and rheumatism, and that in acute dilatation of the heart and chronic dilatation due to failure of compensation, alcohol was a decided evil; he approved of its use as a stimulant only in cases of emergency.

Dr. P. A. Young considered the question from a statistical standpoint, basing his views on the data of insurance and other organizations. The tabulated figures indicated a lower death rate in the total abstainers than in the non-abstainers, drunkards being excluded.

Dr. Foulis held the view that, as a stimulant, alcohol was of little importance in assisting the heart action in chronic disease, as, in his opinion, action was always followed by reaction. He believed that the effect of stimulation on the heart reduced its force.

Dr. Welsh spoke of the effects of alcohol taken in small doses and not habitually. On himself, he found that a small dose interfered with finely co-ordinated movements, and diminished mental power; taken before retiring, it has a decided somnolent effect, and he had known many cases in which it had been relied on as a means of producing sleep.

Dr. Church pointed out that alcohol in disease acts differently from the way it does in health; when administered, it should be in small doses, and carefully watched.

Dr. Claude Kerr wished to ask what Dr. Woodhead would give in place of alcohol. He used it with good effect in diphtheria, and in toxæmia generally; while admitting it to be a poison, he saw no reason why it should not counteract another poison, and claimed that its tendency to lower temperature was the one point against its use in the treatment of diphtheria. He believed that theories on the use and abuse of alcohol would better give place to practical consideration of the subject, and that while there were objections to the use of alcohol, there were yet cases in which nothing could be used as a substitute.

Professor Fraser qualified his previous remarks, stating that he had at first confined his argument to the effects of small doses; large doses were certainly harmful. If alcohol was to be considered a food, it must be regarded as having only a temporary food action; it supplied only certain elements which alone would not maintain nutrition. He wished, rather, to show that alcohol was a medicinal substance with well-defined therapeutic actions, and as such was to be employed.

Professor Woodhead said, in reference to Professor Fraser's statement about the lower mortality from the plague in non-abstaining Europeans, that there could be no comparison between the well-fed and well-housed Europeans and the starved natives in this respect; the difference in death rate was beyond the influence of alcohol. Alcohol used in diphtheria increased the liability to antitoxin rash. He did not wish to be understood as advocating the exclusion of alcohol from the Pharmacopœia; on the contrary, he recognized the existence of conditions in which there could be no substitute for alcohol, but its use should be confined to emergency cases, and it should be prescribed in definite doses and for a definite period.

Dr. J. W. Ballantyne referred to the effects of alcohol on the immature organism, citing the experiments of Féré on hens' eggs, the introduction of alcohol into the egg in the early stages of incubation producing marked teratological results. He had met some cases of human monstrosities which he considered due to the excessive use of alcohol by the parents. It is established that alcohol taken by the mother passes through the placenta to the fœtus very rapidly, and he considered that the action of alcohol reaching the fœtus in this way could not be other than harmful. He also noted the fact that it has been demonstrated that infants born to habitually inebriate women show a high degree of mortality, and, further, that prison statistics show that alcoholic mothers have given birth to healthy children after six or seven months' total abstinence in prisons, this latter fact offering some hope of successful preventive therapeutics.—*The Scottish Medical and Surgical Journal.*

Comments on Tuberculosis in British Lay Journals.—A significant feature of the discussion which has been aroused in Great Britain by Koch's statement with regard to the innocuousness of tuberculous milk and meat as a means of propagating and disseminating consumption is the acute interest which has been taken in the matter

by lay journals. Moreover, most of the comments made have been in an intelligent spirit, and undoubtedly the production of men who knew whereof they spoke, and not, as has been usually the case, a travesty and misrepresentation of the whole subject. The *Saturday Review* of August 3d is a conspicuous instance in point. It contains an article which, while moderate and conservative in the expression of the writer's views, nevertheless estimates Dr. Koch's pretensions to infallibility in scientific research at their true worth. The portion of the article which refers to Dr. Koch's statements at the Congress on Tuberculosis runs as follows: "Professor Koch, who, with all his undoubted claims to respect and admiration as a brilliant investigator, is somewhat of a sensationalist, was stating nothing new or unknown when he informed the meeting that it is not dangerous to eat tuberculous meat or to drink tuberculous milk. It is extremely rare to find what physicians call the primary lesions of tubercle in the course of the alimentary canal. The sputum from consumptive patients is full of tubercle bacilli, these may dry without losing vitality, and, blown about in the fine dust of the air, they are breathed into the lungs of new victims. Here in this fact is another reason for the interference of the State with regard to those already suffering from tubercle, as each of these is a continuous source of infection for others. Professor Koch's main point, that the tubercle of man is an organism distinct from the tubercle of cattle or of fowls, obviously, as Lord Lister points out, is a statement requiring very full investigation. That tuberculous meat and milk are not specially dangerous to eat is little to the point, since bacilli dried from these might gain access to the human body in the usual channel by the lungs. That the bacilli of man, fowls, and cattle are not identical, under the microscope, is again not conclusive, as bacilli of all kinds are notoriously polymorphic, that is to say, change their character and appearance according to the media in which they are cultivated. Moreover, they change not only in appearance, but in properties, so that bacteria taken from an animal, and grown for some time in a medium, may fail to infect another animal of the same kind. Finally, tubercle bacilli are organisms slow in growth and difficult to cultivate, and that bacilli taken from human bodies do not at once infect animals is no certain argument against the essential identity of the organisms. These are questions to be determined finally in the laboratory, and not by formal public discussion; and in the meantime it would be a serious thing if the campaign against tuberculosis were to be relaxed." The foregoing remarks present the subject in a sane and reasonable manner, and it is well that lay journals should procure the service of skilled men to write on medical and scientific matters. Consumption is a subject that closely affects the whole community, and the non-professional mind is able to grasp and comprehend the theories as to its cause and dissemination when stated clearly and simply, as in the article from which we have quoted.

A writer in the *Westminster Review*, July has a well-put together article on this subject, treating it from the point of view of the speakers at the British Congress on Tuberculosis. The contributor to the English monthly says in part: "There is no need here to enter fully into the question of how far tuberculosis in cattle does injury to the human race. Everyone who is in the least interested in the matter knows that this is one of the most fruitful causes of all kinds of tuberculous disease in man. It is evident that the drinking of tubercle-tainted milk is more or less innocuous to the ordinarily healthy person, the probability being that, as the health is good, the milk consumed helps to supply nourishment sufficient to render the system tubercle-proof, if it were otherwise, almost every person in this country would die of some form of tuberculosis, for it is certain that nearly every quart of milk consumed contains tubercle germs, since there is scarcely a byre in the length and breadth of the land in which one or more cows would not be found to be affected. The milk from these tuberculous cows is mixed indiscriminately with the rest of the milking. As it is, perhaps it is not too much to say that every second person is tuberculous in some respect or other, although he may not be aware of it, and there is but needed a sufficiently lengthened condition adverse to health in order to develop the disease into evidence. In the case of children, especially if badly nourished, and weakly adults, this tubercle-laden milk is an ever-present and often fatal danger. This is clearly seen from the fact that children, who, as time goes on, are more and more fed from the objectionable feeding bottle, are the only part of the community in which tuberculosis is on the increase."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 31, 1901:

THE ORIGIN AND FORMATION OF FIBROID TUMORS OF THE UTERUS.

BY MARY A. DIXON JONES, M.D., F.R.M.S.
NEW YORK CITY.

CAN anything be of more importance from a purely practical standpoint than tracing the anatomical and pathological changes that may take place in tissues from infection or inflammation? Normal tissue, when once inflamed, may go on to various and unknown changes and to new pathological formations. Nature never stands still. Life elements are ever active, and in pathological conditions are continually progressing into new-forming growths. No one can tell what these growths may be, or what may be the nature of these new formations, or what changes they may continue to undergo.

Also of inexpressible importance is the fact that infected or inflamed tissues can never be perfectly restored to their previous anatomical condition, nor can they ever again as perfectly perform their normal physiological functions. We often find inflamed tissues changing into fibrous connective tissue, but this secondary fibrous connective tissue can never perform the functions of the original normal structure; and, as I have repeatedly seen under the microscope, this secondary or newly formed fibrous tissue is constantly undergoing change; again breaking down into inflammatory corpuscles, and again forming fibrous connective tissue or some new growth or structure. When fibrous or any other tissue is thus reduced to inflammatory corpuscles or to medullary material, any new growth may develop.

Medullary tissue, or protoplasm, contains the life elements, and *only from these life elements can come any new formation. This is nature's law*, and in her open book we read it clearly.

In this way fibroid growths of the uterus are formed; and it is the only way that they, or any abnormal growth, can be developed. One tissue cannot produce another, nor can one structure give birth to another anatomical formation. It is only from these primal life elements that any new growth or tissue can be evolved.

Nearly a dozen years ago I made the statement that whenever there was a myofibroma, the uterine appendages were diseased, adding:[1] "There must be some connection in the way of cause and effect between disease of the uterine appendages and a fibroid tumor, or uterine myoma."

This assertion I had never before seen made. Soon after I called attention to the fact: "That when there were diseased uterine appendages, the uterus, in every instance, gave evidence of some profoundly abnormal condition." I first observed this in 1887.[2] It was then a little more difficult to realize, though the first case and also the second presented to my mind the clearest and most incontrovertible evidence. Later investigations still more confirmed these assertions,[3] and have now clearly demonstrated that when *there is a myofibroma, not only is the uterus diseased, but it is this disease of the uterus that produces the fibroid growths.*

Fibroid growths are diseased products, and the outcome of diseased conditions. The tissues of the uterus are first reduced to granular or medullary tissue, and from this granular or medullary tissue fibroid tumors are developed. A new growth can only come by some tissue being reduced to its primal elements or to protoplasm.

I will present here a small fibroid tumor of the uterus, surrounded by a few muscle fibers artificially separated.

FIG. 1.—A Fibroid Tumor with a few Surrounding Muscle Fibers. 1 Tumor; 2 Muscle fibers.

These apparently few fibers, when placed under the microscope, reveal the presence of a great number

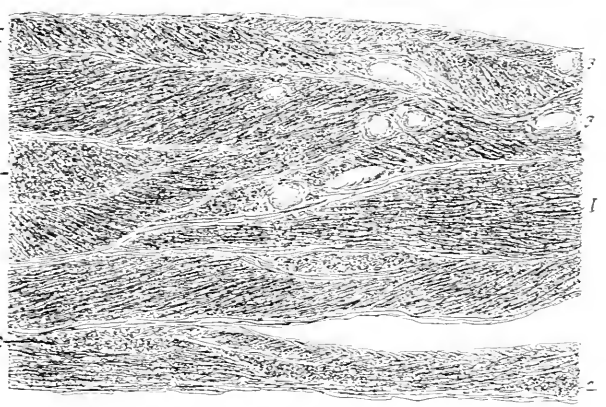

FIG. 2.—The Muscles of the Preceding Figure Magnified, Showing a Vast Number of Muscle Fibers. 1 Muscle fibers partially reduced to granular tissue; 2 Inflammatory corpuscles; 3 Blood vessels.

of smaller fibers. Under higher powers a yet greater multiplication will be manifested.

Figure 2 shows clearly how the muscle fibers from disease or infection are, as anatomical elements, being gradually destroyed and reduced to medullary tissue or protoplasm.

This figure also gives us a little glimpse as to the vast number of muscle fibers there are in the uterus. Every portion of the wall of the uterus, under high magnification, presents almost an infinite number of such fibers. There are countless millions in the whole organ, each one capable of

contractility, and, under special conditions, all can unite in producing one tremendous force, apparently sufficient to overcome the strength and muscular power of the whole human body. So enormous and so wonderful is the muscular structure of the uterus, so powerful in its expulsive forces, that it is used as a figure by one of our most elegant and classical writers.*

The uterus, with its countless number of muscles, is a marvelous formation—each little fiber holding its place, each one showing its own strength, each one so perfect in its structure and beautiful in its formation, that no pen can describe, no pencil portray, nor have I seen the photograph that could exhibit it.

A well-known pathologist lately said to me: "There is nothing in the uterus," referring to its histology and pathology. But the uterus is marvelously constructed in every part of its organization; its muscles, the nerves, the glands, the blood vessels, with their several coats, and the many pathological changes that may take place in them, as well as in other structures of the organ, all call for our most serious and thoughtful consideration and careful investigation. Also the changing conditions of the uterus in performing its special functions tell a story of marvels. The uterus, both in its histology and pathology, presents many subjects of deep interest which are as yet almost unexplored fields.

In this organ is also placed that most marvelous formation, so small, and yet, by some wonderful mystery, contains all the elements of the most wonderful structure, the master work of creation—a human being; to understand any organ of which would seem to take a lifetime of study, and then we would, as Sir Isaac Newton expressed it, be only playing with the pebbles on the shore.

primal elements, and all the other tissues in like manner were showing different degrees of inflammation. There was no normal structure found in any part, and in it there were all the characteristics of a fibromatous uterus, and, at the same

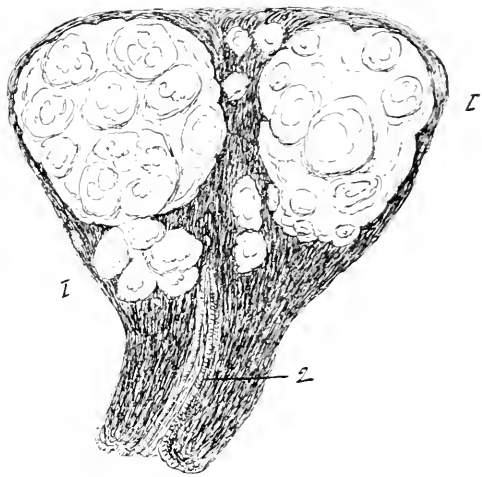

FIG. 4.—A Section of the Uterus, Showing Internal Fibroid Growths. 1, Fibroid tumors; 2, The cervical canal.

time, could be seen the *initial lesions and early changes*.

If any part of the uterus is seriously diseased, we may well believe that other portions are in a similar state. From the outside of this uterus, there were eight tumors developing and most unusually deforming the little structure. When I made a section through the organ, I found a number of groups of newly growing fibroids as represented in Figure 4. The whole organ was growing into worse conditions, and necessarily there would follow only a history of continued and increasing suffering. Prof. W. Gill Wylie did the wisest thing in removing the whole of the diseased structure; new growths were appearing, and more would have been developed with complicating pathological changes.

These tumors were all the outgrowths of this newly formed tissue. They were formations from the primal elements. But for the previous inflammation, and the formation of the new material, there could have been no tumors; but now, after the reduction of the tissues to granular material and protoplasm, fibroid growths were rapidly forming.

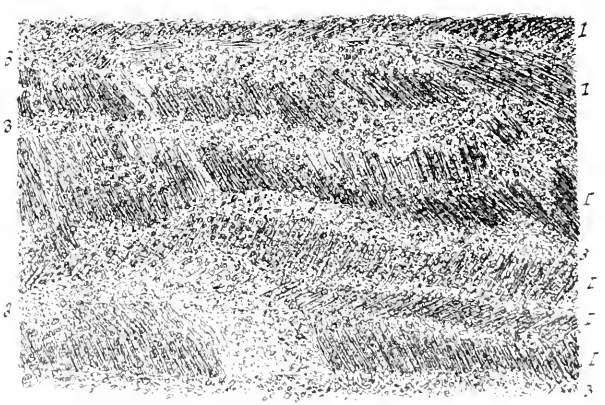

FIG. 3.—Showing a Still Further Destruction of Muscle Fibers. 1, Muscle fibers gradually being reduced to protoplasm; 2, Muscle fibers entirely gone; 3, Between and in the broken-down muscle fibers are inflammatory corpuscles and granular material. ×48.

Figure 3 presents more advanced pathological changes. Much of the normal structure is destroyed. The muscle fibers more completely reduced to granular material, portions of many of them are changing into inflammatory corpuscles, and all showing rapid and progressive destruction.

In other portions of this uterus, I found the same evidences of disease, the same changing pathological conditions, and the same rapid destruction of normal tissue. In every section, from any part that I examined, the muscles were being reduced to their

The cervix proved to be the most diseased portion; there was more intense inflammation than in any other part of the organ, and a greater destruction of muscle fibers. Figure 5 shows the general inflammation existing, Figure 6 the tissues around the glands in apparent suppuration.

In every case of a fibromatous uterus that I have ever examined, the cervix has been the portion that has shown the most profound disease and the most advanced pathological changes. As I said in 1888: "It is only the remains of a sickly uterus, and can be of no service, and may do much damage."

That the cervix should ever have been left in any

* "The sea broke forth as if issued out of the womb." Job, chap. xxxviii., 8.

mode of operation was an unfortunate proceeding. Only the wonderful skill of our great and distinguished surgeons made the excellent results that we have.

For a fibroid to be developed the *tissues of the uterus must first be reduced to medullary elements.*

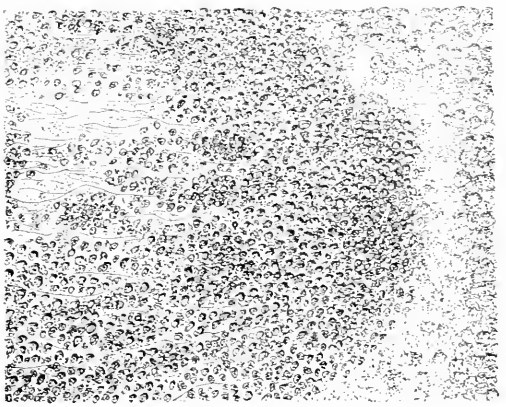

Fig. 5.—Portions of the Cervix Reduced to Inflammatory Corpuscles.

When there is much infection, the changes will be more pronounced and increase more rapidly. The more inflammation the more rapid and the more complete the destruction of the tissues. The strongly built muscle fibers become more and more reduced to granular material, or protoplasm, and when they are in this condition, all is ready for the growth and development of the little fibroid tumors, and the formation of the larger and more solid structures.

Some have put the question as to what year, age, or period of life fibroid growths appear. *It does not depend upon the year, age, or period of life; it is when there is infection and consequent inflammation.* When a tumor appears, it is no indication of the time of life or age, but it reveals the important fact that there is disease. *We see how that inflammation or disease destroys the muscle fiber, and from this breaking down of the tissues come the new formations.*

Figure 7 shows a yet more advanced stage. The muscles are torn apart, swept by some powerful force from their normal position, and many of them destroyed. Many others are reduced to granular material. The infection gets in, and, like some unseen power, destroys the beautiful and fine normal structure, each little muscle fiber, and other fine organizations. Everywhere this unseen and tremendous power is at work, changing and destroying normal tissues. Large portions are already reduced to their primal elements. There they are, whatever we may call them, granular or embryonic material, protoplasm, medullary tissue, by whatever name; no one has yet been able to tell the nature of these little granules or their power; yet these primal elements are so wonderful in their formation that under the microscope they give to this supposed scene of devastation and destruction the appearance of a fairyland of beauty.

All these muscle fibers, after their pathological changes and almost entire destruction, are still beautiful and full of interest. In many places only granular material is left of the almost disappearing fiber. No one can represent the vanishing lines of beauty; sometimes there remains only a spiritual likeness of the former wonderful little structure, or sometimes there is only a shadow of its past formation.

The marvelous changes still go on; the new building commences; some new life product! We are now looking into the very inner laboratory of nature, getting a little glimpse at the marvels of creation, at nature's more than wonderful workmanship—marvelous and past comprehension! There is the granular material, the life elements; but no one can tell their power, their source of strength, what is their next work, or what may be their next formation, or how this may change or eventuate. But from this wonderful material, there begins to grow the little fibroid tumor, not larger than the seed of a strawberry or that of a raisin, and then increasing in size till great structures are formed. (See Fig. 10, the first fibroid tumor ever removed by total hysterectomy in this country.)

Thus we see that a *uterus may from some source become infected, be reduced to medullary tissue, and from these life elements any abnormal growth may be developed.*

This figure gives a yet more advanced view of the gradual destruction of normal structure from infection. How little is left of the normal tissue; it is being reduced to inflammatory corpuscles, to protoplasm, and then will come the new development, some new growth or tissue. Here are the inflammatory corpuscles, showing intense inflammation, yet in many places are left the traces or remains of many muscle fibers filled with granular material, showing how the structure is being gradually and completely destroyed.

This is a still more advanced formation, a more thoroughly diseased uterus, the inflammation going on to ulceration. This is a section from a portion of the uterus (Fig. 10). It was a most profoundly diseased organ; the patient had suffered for many years. The right tube measured ten inches in length, was coiled upon itself, and filled with bloody serum. The closed fimbriated extremity was four inches and three-quarters in circumference. Left tube, five inches in length, was filled with pus, and its

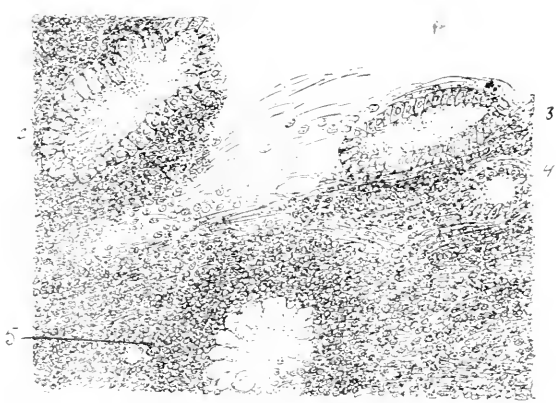

Fig. [illegible] 4. Glands in the Cervix. Intense inflammation and commencing suppuration.

closed, fimbriated extremity was adherent to the left ovary. This general infection and disease is the cause and the accompaniment of the abnormal growth. The tumor weighed thirteen and one-half pounds; with some adjuncts, nearly seventeen pounds.

In the first report of this case, I said:[4] "As the patient lay on the operating table under ether, the body seemed a mere skeleton; the monstrously large and nodulated uterus filled the whole abdominal cavity, extending up to and under the ribs. A large mass of tumors, one three inches in diameter, was closely packed into the pelvis, reaching to the cervix." Also in the first report, I said: "Nothing was apparently left of the uterus except the little undeveloped cervix and the comparatively thin layer of tissue that surrounded the mass of tumors."

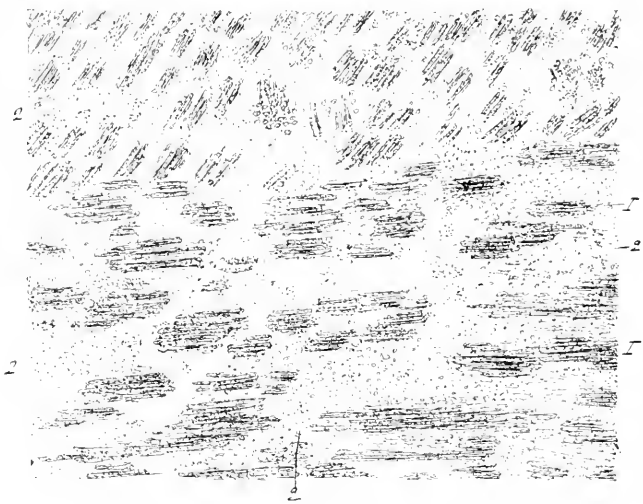

FIG. 7.—1. Groups of Muscle Fibers; 2. Granular tissue. 45

We see, in this representation of a normal uterus, the walls are a little more than an inch in thickness. The walls of this large uterus were not as thick as a piece of blotting paper. The whole structure had been reduced to inflammation, and from these elements had grown the fibroid tumors. I said of another case, a nine-pound tumor removed by supravaginal amputation: "The uterus was scarcely more than a thin sac with intervening membranes for holding these growths."[5]

All these growing tumors were formed by the immense masses of muscles and other tissues in the wall of the uterus, being reduced to granular material and protoplasm, in consequence of a previous condition of disease. The more profound the disease, and the more thorough the reduction of the tissues of the uterus, the more fibroids will be developed. It is the same story: *There is infection, the tissues of the wall of the uterus become diseased, it is reduced to protoplasm, and the fibroid growths are developed.* Whenever infection enters, growths may develop and continue to grow in size and increase in number.

In my investigations on this subject, the beginning of fibroid tumors, I have examined many uteri in various stages of disease, and have always found that these growths are produced by a reduction of the tissues of the uterus to protoplasm or to medullary material. More than six months ago I was convinced that this was the pathological process,[6] but I had no specimens that would prove it or illustrate the subject, nor did I know of any. It was a new field. I commenced at the very foundation, preparing and mounting tissues of fibromyomatous uteri for examination under the microscope. I have continued these investigations right along for months, and have found continually new proofs and clearer demonstrations. Professor William M. Polk kindly gave me the opportunity of examining any specimens in the laboratory of Cornell University and the Loomis Laboratory. He most kindly put both of these laboratories at my service. And the Professor of Histology of Cornell University, Dr. James Ewing, gave me macroscopical specimens of any structures in either of these laboratories that I wanted; and subsequently Professor Ewing cut for me some most beautiful sections of tissues that I had prepared for microscopical investigation, some that he had kindly prepared, and some that he had prepared and mounted.

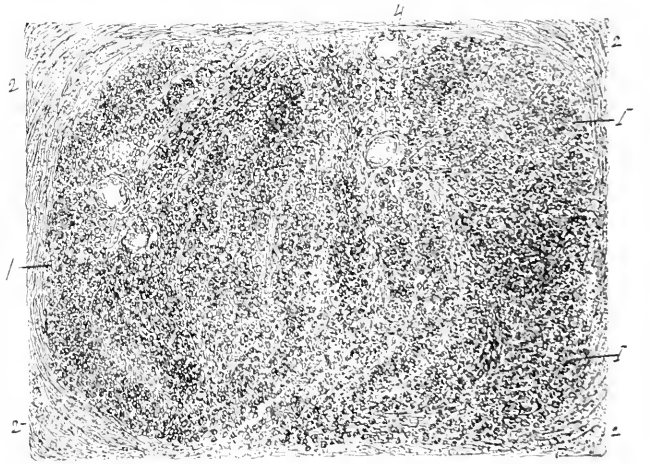

FIG. 8.—1. Muscle Fibers Reduced to Inflammatory Corpuscles; 2. Remaining group of muscle fibers containing granular material.

I studied numerous sections by high and low powers of the microscope. It was a rich field of investigation, full of intense interest and most instructive presentations. It would take pages if I were to attempt to speak of the many most interesting

4. *New York Medical Journal*, August 25, 1888.
5. *New York Medical Journal*, August 25, 1888.
6. MEDICAL RECORD, February 16, 1901, p. 267.

features and histories, but all showing the same wonderful changes. I had only to read what I saw, as Harvey says: "Nature's book is open and legible."

Professor W. Gill Wylie also very kindly gave me the opportunity of examining all the specimens in his laboratory, some large and most profoundly

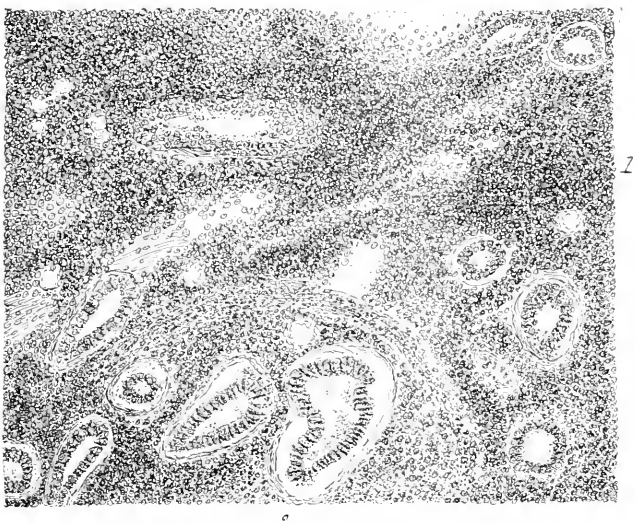

FIG. 9.—1 Inflammation Approaching Suppuration; 2 Glands 450.

diseased structures; and their successful removal showed the greatest triumphs of surgical skill; but I was then trying to look into the beginning of these growths, how they commenced, how they were produced, why they came, and how they had the potency in themselves of such destruction.

All the histological demonstrations prove that

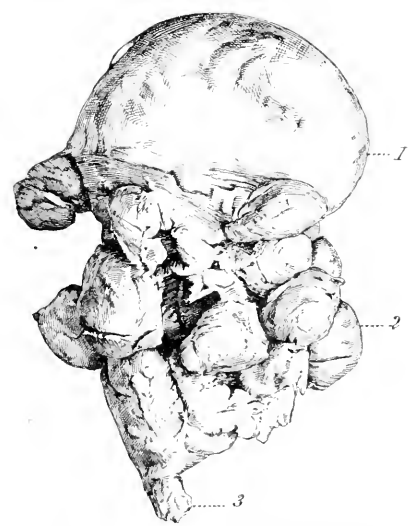

FIG. 10.—Fibroid Tumor. 1. The portion that was in the abdominal cavity; 2. Nineteen smaller tumors that were mostly packed in the pelvis; 3. The cervix.

fibroid tumors are not the giants that produce these results. It is the condition of the tissues that makes the tumors; and it is inflammation that makes the condition of the tissues.

Heretofore it has been the tumors, their nature, and formation that have been the subjects of interest; but the greater consideration is the condition of the uterus where the tumors are formed and where they grow.

We do not and cannot understand fibroid tumors till we look at the surrounding tissues. Yet in our learned textbooks there are hundreds and hundreds of plates of fibroid tumors, and in no one instance have I seen pictured the surrounding tissues. Fibroid tumors can never be understood till we look at the condition of the vital tissues surrounding them; then we see how they originate, how they grow, and what produces them.

We may call them fibroid growths, myoma, fibromyoma, or what not; they are diseased products, changing formations, abnormal and uncertain growths, and continually giving new manifestations of disease. They are composed of muscular and fibrous connective tissues, sometimes more of the one than the other, apparently no fixed rule of structure or composition. They are of uncertain form and ever-changing pathological conditions. I have never examined a fibroid tumor under the microscope but I have found it not only in a condition of disease, but undergoing some form of degeneration. It is the life tissues at work under pathological conditions. The same primal elements

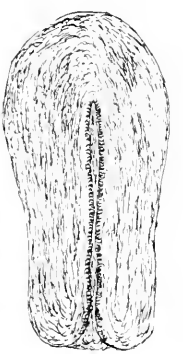

FIG. 11.—A Section of a Normal Uterus.

may, in the same tumor, develop into a carcinoma or any other abnormal growth, as I have shown that inflammatory corpuscles change to cancer epithelia.[7]

Fibroid tumors are never like the first creation of the new and perfect being; they are always the outcome of pathological conditions; the life development of abnormal structures, and always from *some infection*. What a lesson this teaches us as to the great and beautiful principles of hygiene! Any violation of the laws of health—the results remain as surely as the fracture in the crystal glass. Physical sins are not forgiven. "As ye sow so shall ye reap."

Many excellent authors have given us most interest-

7 MEDICAL RECORD, March 11, 1893.

ing accounts of the degenerating changes of fibroid tumors.

Once in removing a fibromyoma of six pounds by total hysterectomy, much of the internal portions of the uterus was reduced to myomatous tissue and apparently a forming sarcoma.

249 East Eighty-sixth Street.

SOME OBSERVATIONS ON MODERN CARDIOTHERAPY.

By HOMER WAKEFIELD, M.D.,
NEW YORK.
ATTENDING PHYSICIAN DEPARTMENT GENERAL MEDICINE, BELLEVUE DISPENSARY.

Recent observations in heart-work, at Bad-Nauheim, Germany, and in the application of some of the newer therapeutic methods, in the same department of medicine, in New York, have led me to formulate for publication a series of physiological principles or laws, long ago suggested and now confirmed by these observations, as the basis of the methods of practice herein treated, many of which I have, for some years, clinically applied in sanitarium and private practice.

Dr. J. Mortimer Granville[1] has presented a physiological law, which is applicable quite universally to morbidly perverted functions, viz., "The best way to stimulate an organ is to incite it to perform its proper function, by performing part of its work for it." To the great majority of cardiac affections, however, the following which I have formulated will perhaps apply more directly, viz., the recuperation of an impaired function of an organ or group of organs is possible inversely as existing obstructions impeding or arresting their normal activity may be removed. As will be seen, the nature of this law is mechanical, but a perusal of this monograph will, I think, convince the reader that the therapeutic action in question is also based on mechanical processes, induced by massage, exercises, baths, medicines, etc.

It is to be observed that the degree of success to be attained in reducing a dilatation and inducing compensatory hypertrophy depends largely upon the amount of work of which the heart can be relieved, and unless the heart muscle has degenerated beyond a possibility of moderate repair, the greater the dilatation, the more marked will be its improvement when a generous portion of its functional task is performed for it, or resistance to it is removed.

The first demand, as well as the first possibility, in a case of heart failure is the reduction of the dilatation, and by the Schott treatment we will begin with the baths, the physiological action of which I will endeavor to analyze.

The essential action of the Nauheim bath is as a cold or cool bath, being administered at from 8° to 13° F. below the temperature of the blood. Baths of this type act primarily more or less mildly to stimulate contraction of the peripheral capillary vessels, *i. e.* those of the superficial muscles and of the integument, the latter constituting the lateral and terminal ends of the former. On the contraction of these peripheral capillaries, the contained blood is pressed into the large splanchnic venous reservoirs, where the existing blood was in a state of stasis, and the arterial blood in meeting the capillary resistance experiences a rise in pressure, which, on attaining a certain point, finally regains entrance to the superficial capillaries, distending them with blood.

With the inauguration of this latter process, the extended action of the *cold*, combined with the stimulating effects of the chemical constituents of the water, the great splanchnic area is stimulated to contraction, thereby pressing forward to the right heart the blood so long in stasis, and coincidentally further raising the arterial pressure and further distending the superficial capillaries, which now become so fully dilated that the arterial pressure falls somewhat, permitting an increase of the heart's output.

On being taken from the bath, the patient is immediately completely enveloped in a hot bath sheet, and an attendant proceeds to administer a brisk frictional rub over the entire person, until the skin is aglow. He is then dressed and retires to his apartment, where he sleeps or rests quietlyf or an hour. As will be seen, the heat of the sheet and the friction of the rubbing combine to produce as perfect a state of hyperæmia of the superficial vessels as is possible, fully compensating for the splanchnic contraction.

Undoubtedly, the foremost of the important physiological factors complicating the heart function is the circulation in the capillary system. It is estimated that this division of the vascular system is approximately from five to eight hundred times that of the arterial system, and it also being the seat of metabolism, the importance of the full capacity of capillary circulation can hardly be overestimated.

Many writers refer to the Nauheim baths as "warm" baths. Air between 80° and 90° F. would be considered hot, but water is a great conductor of temperature, and it is a matter of common observation that exposure, especially of localized areas of the body, to quite ordinary temperatures, if aqueous, often results disastrously, as in getting wet in a warm rain, or in getting the feet wet. This effect, of course, occurs where the immediate effect on the cutaneous nerves is insufficient to insure a reaction, by failing to excite splanchnic contraction. The same general effect may also be produced by unequal refrigeration of an area of the body by evaporation of sweat by drafts of warm air.

The following description of the characteristic physiological action of the Nauheim bath confirms its identity as a *cold* as distinguished from a *warm* or *hot* bath, the difference between cold or cool baths being simply one of degree.

On entering the Nauheim bath, a typical effect of the cold bath is manifested, a slight difficulty of breathing, incident to the peripheral contraction, which quickly passes off with dilatation, followed by an acceleration of the acts of respiration, with a notable increase in their depth and volume. This action necessarily increases the systemic oxygenation, and by so enhancing metabolic oxidation it adds to another effect characteristic of the bath, that of loss of heat, which serves physiologically and directly to compensate for its loss by stimulating more active oxidation of the whole organism. This, of course, is absent in a hot or warm bath.

The Nauheim bath acts directly and ultimately to establish muscular and vascular tone, while a warm bath relaxes the muscles and vessels. The cold bath primarily contracts the peripheral vessels, and secondarily the splanchnics, the reverse being the case with the warm bath, which dilates both.

During the Nauheim bath the arterial pressure primarily gradually rises, followed by a partial fall. It falls primarily with the relaxation of a warm bath.

Oliver[2] observes that a rise of arterial pressure accompanies the Aix-les-Bains douche, which certainly acts as a cold bath, counteracted in a measure by the concussion or massage effect of the play of the water against the body.

During the Nauheim bath the renal function is primarily suppressed, followed by diuresis, with the contraction of the splanchnics. The primary effect of a warm bath is diuretic.

After the Nauheim bath the patient experiences a sensation of warmth; the reverse is the case with

the warm bath, the surrounding air being and feeling colder than the bath.

In the early and latter parts of the bath season at Bad-Nauheim, the weather is both cold and wet, and the air of the bath-houses is at such times often colder than the temperature of the bath. In such cases, it is very difficult to obtain the warm reaction after the bath, and in such event the effect on the patient is more apt to be detrimental than beneficial. Hence arises the importance of the surrounding atmosphere being warmer than the temperature of the bath.

A not unimportant effect of the "cold bath," observed in the Nauheim bath, is the effect of *cold* upon the heart, which is to soothe and slow its action. By a fuller contraction, a more perfect emptying of the cavities and in extension of the period of diastole (period of rest), great benefit and recuperative possibilities are caused. General nerve excitability is lowered by cold, but heightened by heat. That is generally recognized.

The opposite physiological effect of hot and cold baths upon the blood is of interest. Hot baths lower the percentage of corpuscles and hæmoglobin, while the cold bath raises it, and also raises its specific gravity, the analysis of which I will not undertake here.

When the splanchnic vessels are contracted, the blood is deflected from the deep to the superficial parts of the body, and is driven with increased velocity through the muscular areas and their terminals in the skin. We have seen how this can be achieved by the Nauheim or any cold bath.

Other physiological observations, however, impress their importance. Firstly, the capillaries of the muscles are equal to those of the skin and the intestines combined. Secondly, during periods of rest, it has been roughly estimated that the quantity of blood in the various organs of locomotion is about thirty-six per cent., the other sixty-four per cent. lying in the roomy reservoirs of the abdominal and thoracic cavities. During activity, however, the amount in the muscular system is raised to sixty-six per cent. of the total volume of blood.

The above physiological facts suggest the need of a safe form of muscular exercise, and Schott's adaptation of the Swedish exercises of Ling meets the indication. The application of these exercises is, however, so delicate a procedure that there is hardly any line of demarcation between that which will bring about contraction of the heart muscle and the slight overexertion which will cause increased dilatation, the opposite of what is desired.

The graduated mountain climbing, first suggested by Stokes,[32] and put in practice by Oertel[21] and the Schotts, plays an important part in the latter stage of the treatment, when the compensation has been largely restored by the above methods. Mountain climbing, as used as an adjunct to the Schott treatment, at Nauheim, is applied only to cases of the minor heart lesions, especially when complicated by obesity, suboxygenation, etc., and as consequent to the divers processes that cause diminution of the caliber of the superficial vessels. When utilized at all it is applied as the final stage of the treatment.

Notwithstanding the enormous total capacity of the capillaries of the muscles, they are the smallest in caliber in the body, and it is a common observation that when the muscles are at rest, and when, moreover, exercise is insufficient, as in sedentary occupations and in cases of cardiac debility, where idleness and inactivity are enforced, the blood manifests a strong disposition to collect in the internal vessels, resulting in various diseases of metabolism.

It is well known to physiologists that the capillaries of the muscles are so small that, when not distended with blood, as when the muscles are inactive, it is impossible for the red corpuscles to traverse many of them, the result being that suboxidation diseases of metabolism are so common among sedentary and cardiac patients, and this explains why the induced contraction of the splanchnics and the Schott exercises have proved so beneficial to the great mass of cardiac patients suffering from fatty degeneration of the heart, liver, and kidneys, which is due to a condition of oxygen famine, and is often complicated with uræmic symptoms, as a direct sequence. To a consequent state of suboxidation are largely due the subnormal temperature and low resistance to cold observed among subjects of peripheral anæmia.

I will not attempt to describe the Schott exercises here, they having been so many times described and illustrated, in detail, far better than I could do within the limits of this monograph.

To summarize the combined effects of the Schott treatment, baths and exercises, the fact is developed that all act to one end, the rehabilitation of compensatory hypertrophy, not by increasing the demand on the organ, as we would do to induce hypertrophy on striped muscular fiber, nor like that which produced the original cardiac hypertrophy, but by lightening its task, lengthening its periods of rest (diastole), slowing of the rate of contraction, and by lessening capillary resistance and arterial tension, we obtain a more perfect contraction of the heart muscle, with diminished effort, increased output, and diminution of the residual blood.

A thorough discussion of the physiology of muscular fiber as related to muscular tonus and exhaustion is not permissible here. However, in order to develop a point, I will quote from Sanderson:[28] "Exhaustion may be defined as a condition in which the normal relation of tension to length is altered. An excited muscle requires when exhausted, a less weight to extend it to a given length than it did before." "The effect of muscular fatigue is to increase the equilibrium length of the excited muscle." Deducing from these established truths, we are justified in concluding that the phenomenon of heart dilatation is a condition of increase of the equilibrium length of the muscular fiber, due directly to *fatigue*. Such being the case, the local indications are decrease of work, increase of the rest period, and correction of function, in order to promote nature's process of recuperation.

Having now established the physiological status of cardiac dilatation, and the nature of the action of the Schott treatment, I trust the reader will grant that I am justified in assuming that, at least prior to the failure of compensation, the heart encountered a resistance out of proportion to its functional capacity, it probably having been weakened or embarrassed by valvular incompetence, stenosis, or what not. Whether this resistance occurs in the arterioles, the capillaries, the portal system, or the kidneys is not so important, except from a therapeutic standpoint; until relieved the heart must cope with a disproportionately high arterial pressure, and as is always the case under such circumstances, exhaustion, dilatation, and failure of compensation must ultimately follow.

A contemporary has affirmed that the general reversal of pressure, as diminished in the aortic and increased in the venous system, that obtains in cases of severely impaired compensation, confirms his belief that no circulatory resistance is present,

and that no undue arterial tension preceded the compensatory disturbance.

In opposition to the above theory, I will state that in all those diseases complicated by high arterial tension, principally those of the so-called gouty and rheumatic series, in diseases of the liver and kidneys, and in the stenoses of the intra-cardiac orifices, the heart primarily hypertrophies from the overstrain thereby induced, and ultimately dilates from consequent fatigue. Also, when the arterial pressure being normal, as valvular incompetence is developed, and a part of the blood of the ventricle regurgitates, on contraction, the heart, in its attempt to maintain compensation, overworks in pumping against a peripheral or visceral resistance, which in such cases rises above the ratio, and becomes out of proportion to the diminished pressure and force of the heart's output, further reducing it and increasing the residual blood.

It is evident that arterial pressure falls directly with the failure of the heart, the resistance to aortic flow remaining the same, due partly to the enfeebled force of ventricular pressure, and partly to greater adequacy of the diminished caliber of the arterioles and capillaries to the reduced flow of the arterial stream. This explains why the peripheral resistance of states of impaired compensation is not apparent, and yet that the burden of the heart's function is so lightened by an induced hyperæmia of the peripheral vessels, that the heart recuperates from its fatigue.

Drs. W. H. Thomson,[31] Beverly Robinson,[26] and J. M. Bruce[4] have recently contributed valuable monographs, calling attention to hypertrophy and failure of the heart, directly due to peripheral resistance, consequent to general vascular disease.

Oliver[22] goes so far as to declare: "An extremely common if not invariable concomitant of cardiac irregularity is increased peripheral resistance, as expressed in the mean arterial pressure being raised and in the venous pressure being relatively or absolutely lowered."

In the event of failing compensation, the arterial pressure should always be gauged, as heart strain caused by stimulants, especially digitalis, by increasing the force of the cardiac function, may hasten fatigue dilatation, unless the circulatory resistance be first reduced proportionately to the decrease in strength and of the endurance of the heart.

We have in peripheral hyperæmia an explanation why digitalis is so much more beneficial and effective when administered in connection with the Schott treatment, as well as how cardiac recuperation is made possible, *i. e.* by giving the heart relief from the disproportionate circulatory resistance and its resulting muscular fatigue. Normal and even subnormal blood pressures offer no exceptions in such cases. Diminished caliber of vessels consequent to thickening of the vascular walls (arteriosclerosis) (arteriocapillary-fibrosis), thrombosis, embolism, changes in the blood itself (as regards separation of its elements, viscidity, etc.), acute and chronic congestions of visceral organs, and many other conditions might be named which more or less complicate the freedom of circulation. Mechanical strain of the heart due to violent and exhausting exertion produces dilatation directly, by inducing acute fatigue. Thus we see ample illustrations in daily practice.

Galabin[10] calls attention to increase in arterial pressure and in the labor involved in the heart's contraction incident to the impediment to the circulation, due to the altered quality of the blood, as occasionally occurs in the early stages of acute nephritis.

The above analysis of the physiological action of the Schott treatment makes it manifest that the essential beneficial results obtained are not due to percussion, as declared by Heitler[14] and Baruch.[3] And though I acknowledge that pressure of the abdomen by reflex action of the splanchnics proves a valuable means of resuscitation in collapse, especially when visceral venous stasis is marked, I fail to see how any ordinary percussion, as used in physical diagnosis, could accomplish such an effect to any perceptible degree, nor do I see how any permanent good could be realized from such a transient stimulation of the heart reflex as is claimed by Abrams[1] and Baruch.[3] It may also be said that simply slowing of the heart's action alone is of little value, unless the resistance to circulation be reduced in ratio to the diminished heart function.

It may not be amiss here to suggest that the physiological result of blood-letting as practised by the old-time physicians really accomplished, in one respect, the same end as the Schott methods, in that it lowered arterial pressure by reducing the total quantity of blood in the body, which often proved so important in relieving the stress that the serious results of diminution of the vital fluid were, for the time being, at least, overcome. It may also be said that the essential effect of the chemical constituents of the Nauheim bath, in the expansion and distention of the great vascular areas of the muscles and skin, has its analogy in the methods of "counter-irritation" (cupping and vesication) of "ye olden time," as well as in the pine-needle, mustard, and capsicum baths of the present day.

One of the incidental results of the Nauheim bath—namely, its effect on rheumatism—is of great physiological interest. It is a not unusual observation in Nauheim for patients, on taking their initial baths, to have an attack of acute or subacute rheumatism precipitated, of which the exact nature of the physiogical action involved is somewhat obscure.

It always occurs when the patient is on the verge of an attack and when the state of the blood alkalescence is low. A question arises. Is rapid production of peripheral hyperæmia the active cause? In two cases this would seem to be the case, for the subjects were both robust men who took "Sprudel" or carbonic acid baths, unpreceded by the plain saline baths. One was not a patient, although both had rheumatic histories; the first mentioned simply took the baths for the novelty and the pleasure of it; both were inclined to plethora and obesity. The clinical result suggests that the previous freedom from the disease was due to the general torpor of the general circulation, especially that of the muscle arterioles and capillaries, which upon being distended with blood, the acid factors are carried to the periphery and the extremities in sufficient quantity to meet the characteristic requirements of the disease. If this hypothesis be the true one, it throws light on the common complication of rheumatism by endocarditis and other visceral inflammations, suggesting that peripheral anæmia determines the rheumatic processes to the visceral organs, and, conversely, peripheral circulatory activity favors articular and cutaneous affections. This hypothesis would hold good as well in gout as in rheumatism, and it involves all diseases of the so-called gouty and rheumatic series which interchange manifestations.

Another case coming under my observation in Nauheim rather suggests a different *modus operandi*. A thin, pale, and weak woman from England, with a rheumatic history, and coming from a gouty family, was brought to Nauheim for impaired compensation, complicating a valvular lesion. She developed a

severe acute rheumatism after her first bath, which so prostrated her for the entire season that she was unable to continue the baths, and was taken home in October, much worse for her sojourn. Her powers of endurance and reaction were low, and her first bath was the plain brine bath with which most patients begin the treatment, the temperature of the bath being about 92° F. This temperature was not low, but was manifestly too low for her, and undoubtedly her attack was due to spasm or tetanus of the peripheral vasomotors, which, according to physiologists, acts analogously to muscular strain and fatigue, in which sarcolactic acid is formed. This acid by its irritant action serves to prolong and continue its own primary effect. The incidental spasmatic or tetanic contractions of the peripheral capillaries, by impeding circulation, so reduce metabolic oxidation that the rate of oxidation of the formed acids is below the rate of their generation, and so the disease continues progressively.

It is proper to mention here that I have long observed in the so-called acid dyscrasia that its subjects are unusually prone to superexcitability of the vasomotors, and are supersusceptible to shocks of cold. In these cases it is of paramount importance to precede the baths with a course of alkalies or of alkaline mineral waters, continuing with a lighter course, owing to the transient nature of agents acting to such ends.

In cases of lowered vascular tone also, we meet with a condition of remarkable susceptibility to cold, and the excited contractions of the peripheral vessels are excessive in degree and in time length. The contractions vary in approximate ratio to the degree of the relaxation. This is the usual cause of taking cold after hot baths.

An important and constant symptom of the dominant effect of the primary (peripheral) contraction, in which the splanchnic reaction is deficient, is albuminuria, which is due to renal congestion, coexisting with peripheral anæmia, and depending upon the intimate relations existing between the peripheral and renal vessels. The suppression of the renal function when "taking cold" (peripheral contraction) is a common observation.

Therapeutists quite universally recognize the intimate relationship existing between diuresis and diaphoresis. It is almost impossible to cause one action without, in some degree, complicating the other.

In cases of exaggerated reaction to cold, as above described, the temperature and chemical strength of the bath should be heightened and its duration reduced, proportionately to the patient's susceptibility and his powers of reaction. The physician however, should never under such circumstances yield to the temptation to give up the bath entirely, for it must be borne in mind that one of the prime effects of the bath is the production of a lowered state of nerve excitability, together with its well-known effect of slowing and quieting the heart. The bath, therefore, may be begun at an indifferent temperature, and as it is gradually lowered, we lower the state of nerve excitability contemporaneously.

I have already mentioned the relation existing between general nervous states of hyperexcitability and lowered alkalescence of the blood, and the relief derived from alkalies. In this connection, I wish to record an observation: *i. e.* the degree of susceptibility to acids is so great in many cardiac patients who present no particular symptoms of the so-called acid dyscrasia, that even the variations in the acid and alkaline tides are responsible for well-defined symptoms. Particularly has this been observed in the early morning, after the patient has experienced the longest fast in the twenty-four hours, when are developed restlessness, a cough, palpitation, dyspnœa, etc., which are singularly removed either by taking food or alkalies. The effect also from the ingestion of acid foods or beverages, and from gastro-intestinal acid fermentation, produces the same results, only in a more marked degree.

Physiologists have observed that the irritability of the heart is lowered directly as the oxygenation of the blood, a weak heart being an inevitable result of chronic suboxygenation. We are also informed that the oxygen-carrying power of the blood is lessened as the alkalescence of the blood is lowered. Therefore, by a course of alkalies, we may expect to favor the increase of the oxygenation of the body in general, and incidentally raise the state of irritability of the heart muscle, thereby improving its functional action.

Ringer[25] also found that a definite amount of calcium and potassium salts must be contained in the blood in a fixed proportion to admit of the normal functional action of the heart muscle. Acids weaken the contractions.

The normal alkalescence of the blood favors the integrity of both the cardiac rhythm and the vascular tone, therefore it must receive the attention its importance demands.

One of the greatest problems of cardiotherapy is the early treatment of cases, where the prostration and the failure of compensation are extreme, and the circulatory balance approximates that of death, so low is the arterial pressure and so marked is the venous stasis. The heart must have relief from its labors and yet the circulation must be maintained. None of the vital fluid can be spared, the degree of prostration makes both the baths and the exercises of the Schott treatment impossible, and often the further stimulation of the heart by heart tonics is dangerous, the heart being already greatly dilated from excessive fatigue. Consequent to the stagnant circulation, the economy is becoming uræmic, and is suffering generally from deficiency of the oxygen processes of metabolism.

My experience has been that, in these very extreme cases, a fair degree of peripheral hyperæmia can be attained by light, dry, frictional brushing of the entire surface of the body, gradually increased in intensity, until a bright glow of the skin is produced. The direct effect of this on the heart is remarkable, and it is in the direction of the Nauheim bath in its results. This process is followed later by massage, of the whole body in which particular attention is given to the muscles of the arms and legs, serving to promote hyperæmia and oxidation in the muscular tissues.

Another method of benefit in these cases is that of lowering of the arterial pressure, by means of the application of friction, or dry cups, to the lower dorsal and upper lumbar region of the spine. The success of this method, in the hands of the late Dr. J. K. Mitchell[29] of Philadelphia, in the relief of pain in the treatment of rheumatism, led him into the error of formulating the so-called nervous or spinal theory of its etiology. Physiologists do not inform us other than of the effect of lowering of arterial pressure, and I have no theories to offer as to its *modus operandi*, except that I have not observed any depression of the heart's function from it. It may act through the nervous (sympathetic) system, similarly to nitroglycerin, to dilate the superficial arterioles.

My own practice has always been never to permit a patient to suffer from any dyspnœa which could be prevented by the inhalation of any quan-

tity of *nascent* oxygen, which can be furnished from the generating apparatus which I place convenient to the patient's bed. The importance of this, in these cases, is so great that I often use a continuous stream, by direct tubal inhalation, or a highly impregnated atmosphere of the room, to meet the indication. The free use of *nascent* oxygen in these cases vividly elucidates to the attending physician the pernicious effect, on the prostrated patient, of an unrelieved dyspnœa, acting, as it does, to produce fatigue, and as also owing to the consequent suboxygenation. I have never observed an ill effect from too much oxygen. I am, however, careful to wash the gas thoroughly, through four bottles of water, one of a saturated solution of caustic soda, and finally one of lime water, the bottles placed in the following order: water, soda solution, three bottles of pure water, one of lime water, and lastly an empty (drip) bottle.

I am very particular as to diet, and in limiting the patient's digestive effort to the most highly concentrated food, of the highest nutritive value, and in my experience, myosin-albumin, prepared after the recipe of Forbes Ross,[27] peptonized, has proved most successful. After the convalescence is established, I am particular to exclude all the acid foods and beverages, as well as most of the fermentable carbohydrates. As in all cases of cardiac debility, especially associated with suboxygenation, the proneness to acid fermentation is very marked, and it often occurs insidiously in the intestines unobserved. The quantity of cellulose, especially, must be minimized, it being very difficult of digestion.

A subject which I deem of supreme importance in diseases of the heart is the condition of the portal system. I think balneologists are extremely negligent of the proneness of this branch of the circulatory system to become a seat of stasis, which is so little affected by the Schott treatment, and must be counteracted with cholagogues. Dr. Bezly Thorne[4] is prominent among those who have urged giving greater attention to this point, and to the importance of observing the fæces for the biliary coloring, which is so often absent in these cases.

The intimate relations existing between the circulation in the peripheral and renal vessels was long ago observed and set forth by Senator,[6] and later, especially in modern cardiac practice, it has become quite generally recognized

After the physiological effect of the Schott treatment is attained, and continuing while peripheral hyperæmia continues, the urinary function is generally normally active, occasionally hyperactive.

During a period of broken compensation, as above illustrated, however, anuria is a common and almost universal symptom, and prior to the production of some degree of peripheral hyperæmia, we are compelled to take active measures to dilate the peripheral vessels, by medicinal means, and, for this purpose, the proper adaptation of nitroglycerin is of the greatest value and utility. In the use of this remedy, it will be found that the smaller doses, administered uninterruptedly, will generally suffice to guard against renal congestion and anuria, when if permitted to occur, often the largest doses will only with difficulty restore diuresis.

In connection with the renal function, it may be observed that attention to the "hydrostatic balance" of Oertel[3] is of the greatest value. If physicians will cause an accurate account of the fluids imbibed and excreted to be kept, they will be able to compute any amount of fluid that may be exuding into the tissues, and as a prophylactic and therapeutic measure may reduce the fluids imbibed to an amount equivalent to the amount excreted.

Pulmonary congestion, complicating failure of compensation, as well as the resulting hemorrhages, I often treat successfully by oxygen inhalations alone. Cold applications to the chest, in such cases, have within my observation proved very deleterious, and predisposing to thrombus and emboli.

In addition to the nitroglycerin mentioned above, I make liberal use of digitalis, strophanthus, sparteine, quinine, strychnine, potassium iodide, and other remedies, until a degree of compensation is established, and the Schott treatment is well under way, when it can generally be depended upon alone.

Following, in regular order, a graduated course of mechanical treatment, leading up to the Schott treatment proper, I follow the massage, above described, with some specially adapted Swedish movements, very carefully administered, while the patient continues in the recumbent position, in bed, principally flexion, extension, and a rotary movement of the arms and legs.

As soon as the improvement of the patient justifies a daily sitting up in bed, I take advantage of it to begin a preliminary bath, and while sitting on the side of the bed, the patient places his feet in a carbonized brine bath, in a vessel on the floor, of sufficient size to accommodate the feet and to permit the water, which is at blood heat, to reach nearly to the knees. This foot bath is very effectual in accelerating the circulation of the lower extremities, and it produces a well-marked peripheral hyperæmia of the region between the knees and toes, somewhat lowering arterial pressure and relieving the heart.

Shortly following the above-mentioned procedure, I generally find patients are able to take the first full Nauheim bath, it being of course necessary that the bath room should be convenient to the bed chamber, and in these serious cases I have the patient *carried* to and from the bath and *assisted in and out of it*. The attending physician, who should be provided with potent restoratives, should hold the patient's radial pulse, during the bath, and act quickly should collapse threaten. This bath may be begun at blood heat, or at an indifferent temperature, and lowered one degree each bath day, subject, of course, to the indications of the heart and general condition. Such precautions are relaxed with the improvement.

It is customary to begin a course of baths with the temperature relatively high, the chemical strength low, and the duration correspondingly short, but in instances of very low vitality, diminution of the powers of resistance and reaction, together with exaggerated excitability of the peripheral vasomotor nerves, the chemical strength must be raised in order to overcome the depression of the cold.

On removal from the bath, the patient should be carried back to the bed, and all the conditions of environment made favorable to an hour's sleep or quiet rest. The action of the bath is conducive to sleep.

An important effect of the chemical ingredients of the bath is the production of increased tolerance to cold (hardening), and they are also most effective in enhancing vascular tone and oxidation, making possible lower degrees of temperature, as well as directly adding to the stimulative effect of the cold on the peripheral vasomotor nerves.

Great care must be taken never to cool the patient more rapidly than the consequent increasing oxidation will compensate heat for, and the gradual lowering of the temperature of the bath should not exceed the rate of restoration of vascular tone. A pronounced sensation of chill is always indicative of shock, the reflex act of determination of blood to the periphery being apparently paralyzed. The

warm reaction which should always follow indicates the reflex contraction of the splanchnics, determining the return of the blood to the periphery. A mild shivering sensation, however, generally accompanies accelerations of oxidation, as produced from loss of heat, and is not necessarily significant of injury.

In one respect, especially, the baths are indispensable, *i. e.* in the restoration of tonicity to the muscles of the heart, the abdominal walls, and the vascular system.

During the period of prostration, we confine the patient to the horizontal position, in order to escape the extra-cardiac effort required to maintain the circulation against the force of gravity. However, when the patient regains enough strength to reassume the erect position, it is paramount that we restore the tonicity to the splanchnic area. The tonic contraction of the relaxed and dilated splanchnic arterioles and veins counteracts the disposition to œdema of the lower extremities, otherwise present when in the feet down position. The hydrostatic stress of gravity is such, that relative rigidity of these vessels, as well as of those of the abdominal muscles, is necessary to the restoration of a degree of compensation sufficient to insure against stasis of the ascending venous column, when in the erect position.

Another effect of the cold bath, the lowering of the excitability of the cardiac muscle, is of especial value in irregularity of the heart, and this cannot be replaced by the exercises. It is true that both regularity and slowing of the heart may be attained by the application of ice bags to the precordium, as well as by the baths, but notwithstanding the fact that the heart muscle cannot be tetanized, it is certainly not a safe procedure. I have observed a case where the application of ice for such purposes, shortly following a pulmonary congestion and hemorrhage, by increasing the congestion, favored the formation of a thrombus from which the patient soon after died,

Some members of the profession refuse to be convinced that there can be any real virtue in the direct action of the Nauheim bath; *firstly*, all previously accepted methods of establishing the size of a heart were discredited when applied to a demonstration of the reduction of dilatation by the bath; *secondly*, the results obtained have been ascribed to the action of the heart reflex, as stimulated by diagnostic percussion, instead of to the bath; *lastly*, many skeptics give expression to their failure to see how any *permanent* benefit can be attained in organic heart disease by the Schott methods.

It is true that the tonicity induced in the muscular and vascular systems may be gradually lost again, on debilitation of the patient by the relaxing effects of hot weather, etc., the peripheral circulation may be depressed by the action of sudden, severe, or unequal exposure to cold and wet, and fatigue dilatation is also again possible.

We have seen, however, that the principal therapeutic action is the rehabilitation of the peripheral circulation, by gradually increasing distention of the vessels of the locomotor muscular and cutaneous systems. Hermann Weber,[b] Bezly Thorne,[31] and others have observed that by the combined treatment, baths and exercises, not only diminution of caliber of arterioles and capillaries is overcome but also instances of absolute obliteration.

Under all ordinary circumstances, in the subjects of organic heart disease, the altered mode of life is such that when the full caliber of the peripheral vessels is once restored, it is a matter of comparative ease to continue the effect, making it approximately permanent.

I have hinted above at the ultimate curative effects of the restoration of the functions of oxygenation, oxidation, and nutrition in its broadest sense, the re-establishment of compensated circulation and the recuperation of the cardiac muscle.

Taking into consideration the above, with all that it implies, the action on the blood itself, on digestion, and on organic functions in general substituting a progressive improvement for a progressive decline, it requires no strain of the imagination to perceive the genesis of cardiovascular repair.

I have long been convinced that cardiovascular disease, as manifested in the heart and blood vessels, including the highly vascular organs, especially the spleen, liver, kidneys, and the lungs, is more homogeneous, both in etiology and pathology, than is generally conceded. While I recognize the inflammatory processes instituted by pathogenic bacteria, I am confident that the chronic processes which we term endocarditis, endarteritis, arteriosclerosis, arteriocapillary fibrosis, atheroma, cirrhosis, and calcareous infiltration of the vessels, and in many cirrhotic and inflammatory diseases of the organs, are due to chemical irritants in the blood, and principally to excess of organic acids. These acids are imbibed in acid foods and beverages and are generated by gastro-intestinal fermentation and by muscular activity, and may be accumulated to excess by renal and cutaneous retention, and by metabolic suboxidation. A more extended discussion of these etiological factors must be deferred to a later paper. However, their recognition is important in both the prophylaxis and the therapeutics of these diseases.

The general disposition of the animal kingdom, in its continued metabolic changes, as is well known to biologists and medical men, when relieved of morbid agencies which disorganize tissues or derange organic function, is to recuperate and gradually resume the normal processes. We know that even fatty degeneration of an organ, when artificially induced by a known process of suboxidation, in many cases, when the process has not already destroyed the organ to an extent incompatible with the performance of its function, will undergo restitution when the etiological factor is removed.

To this physiological action the cardiovascular system, barring advanced arteriosclerosis, arteriocapillary fibrosis, and calcification, offers no exception.

Observant practitioners of cardio-therapy are constantly meeting with surprises in the remarkable repair that occurs in all classes of cardiovascular disease, after many or all of the predisposing and exciting chemical and physical causes have been counteracted or removed.

To the late Professor F. W. Beneke of the University of Marburg we are indebted for the first experiments and for the first exposition of the beneficial effects of saline and carbonated waters on the subjects of rheumatic endocarditis and its resulting impairment of compensation; to the late Dr. August Schott of Bad-Nauheim for the discovery and demonstration of the physiological action of the baths, and to him and to his surviving brother, Professor Theodor Schott,[29] for the foundation, application, demonstration, and exposition of the systematic methods of treatment of heart disease in general, by a combined adaptation of brine and carbonic-acid baths and exercises, which now bear the name of "the Schott treatment of chronic heart disease."

The theories of the physiological action of temperature, chemical irritation, and mechanical stimulation of the periphery, and of exercise on the circulation,

metabolism, and other processes and of the relations of oxygenation and hyperacidity as herein set forth, have been independently arrived at and applied successfully in practice, for many years, by the author. Owing, however, to the adverse criticisms of them, by fellow practitioners, their exposition has been deferred until the present time, it being now possible to include their confirmation by other original investigators and observers, whose independent work I also acknowledge.

In concluding, a word of protest should be entered against the promiscuous administration of the Schott bath and gymnastic treatment of heart disease, by bath establishments, masseurs, nurses, and other irresponsible persons, as is now becoming so common, independent of competent heart specialists. It is evident to the discerning mind, that heart disease with its complications, is just as difficult to treat properly and successfully by the Schott methods as by medicinal and other measures, and, moreover, these methods should never be applied entirely independently of medicinal treatment.

This regimen, however valuable an acquisition to our previous resources in this line of practice, requires as much if not more fundamental knowledge and skill than the older therapeutic methods, which have always been admitted as requiring the most delicate and precise adjustment and adaptation of any in the practice of medicine. Errors of management of cardiac diseases are just as fatal in one branch of treatment as in another, and the empirical and promiscuous administration of the Schott treatment is dangerous in the extreme.

We have special hospitals for the ruptured and crippled, for skin and cancer patients, eye and ear cases, and other departments of medicine, but none for those who, above all, require a specially equipped institution.

Here is the opening of the century, for philanthropists, to erect an institution which will fill a long-felt want.

The education of the cardiac patient to conform his future life to the limitations of strength and endurance necessary to the maintenance of compensation, in cases of existing serious organic lesions, is also the province of a special institution.

In a recent round of inspection of the bath establishments of New York which profess to administer the Nauheim bath, I failed to find one which was equipped with the correct shape of tub for the proper administration of the bath, all of them making it necessary for the patient to assume too much of a recumbent position while in the bath. This also is the great fault of the tubs in private houses, such tubs also, owing to the wrong location of the inlet, making it impossible to use ready charged water, which is far preferable to the use of acid cakes.

The uneven porosity and consequent solubility of acid cakes and the unequal dissemination of the carbonic acid through the water, make their use unreliable and far inferior to the methods of charging closed tanks of water under pressure, by liquid carbonic acid, which evenly charges the water, and and it can then be drawn into the tubs, as desired, for either still or flowing baths. Such a plant is another possibility for special institutions. I should prefer an evenly applied pine-needle bath to an uneven carbonic-acid bath, as is ordinarily that produced by the use of acid cakes.

I have been interrogated by a colleague as to whether the newly introduced adrenal extract will supersede the Schott treatment, to which I answer in the negative. It is apparent that this new heart tonic has none of the immediate physiological actions of the Schott treatment, yet, if on ample demonstration it fulfils our anticipations for it, it will undoubtedly largely supersede digitalis and strophanthus, and will serve both to augment and to perpetuate the effects produced by the Schott methods much better than either of them.

THE FUNCTION OF THE TONSILS,* WITH A FEW SUGGESTIONS REGARDING THE DIFFERENTIAL DIAGNOSIS OF TONSILLAR AFFECTIONS.

By R. C. MATHENY, M.D.,
GALESBURG, ILL.

In a town of eight hundred inhabitants there are four practising physicians. I do not know just what their relative popularity is, but as they are all making a good living it may be supposed that the practice is about equally divided. One of them said to the writer not long since that he had performed eighty-five tonsillotomies in the last year. He said if there is a tonsil to take out he takes it out, and he attempted to justify his practice by saying that in a certain textbook it is recommended. I am sorry to say that he spoke nearly the truth. For you would infer from reading the book that any tonsil which can be seen is hypertrophied, and a hypertrophied tonsil should be removed. Without commenting on the safety or unsafety of following this advice, my purpose is to plead for a more intelligent and conservative treatment of the tonsils and tonsillar affections.

From not knowing what the function of an organ is to saying it has no function is but a short step; or, if not exactly saying that the organ has no function, at least treating it as if it had no function, which amounts to about the same thing. And this has been especially the case with the tonsils. Until recent years most authors confessed not to know the function of the tonsils. Many theories were advanced, some of them vague and indefinite. But as they were mere assumptions they were not generally accepted. It was perhaps natural after a certain familiarity with the tonsils, and the familiarity had brought no definite knowledge as to just what they were for, to take a step farther and to think they have no function, or, at least, a useless function, and so to look upon them as foreign bodies, and their presence inimical to the general bodily welfare. And so the tonsils came to be looked upon as wholly superfluous, and therefore were treated with disrespect. Of course, if they performed no useful function, they must be an evil, and if an evil they should be eradicated. We have become very bold with our increasing knowledge, and we do not hesitate to say of many of the structures of the human body that they are merely relics of a bygone age, and that they are only atavistic tendencies inherited from the time when we were not the highly evolved creatures we are to-day.

But notwithstanding the mistakes of the past in the domain of medicine and the bold but unjustifiable plunges of the aseptic surgeon, both medicine and surgery are making advances to the benefit and relief of the long-suffering race.

What are the functions of the tonsils? Before attempting to answer this question it might be well first, to state what they are. Before proceeding further, let me say that what is said hereafter refers to the faucial tonsils only, and not to the pharyngeal and lingual tonsils, and no reference is made to them unless specifically stated.

The faucial tonsils, then, are the two masses of lymphoid tissue, situated between the pillars of the fauces, having a not very uniform shape, and varying also greatly in size. It is almost impossible to describe a typical tonsil, about the only uniform characteristic being its structure, and yet the very structure is one which undergoes certain progressive changes throughout life, which are common to all lymphoid tissues. Then, besides, lymphoid tissues undergo very rapid and marked changes under pathological processes, and it is impossible, often, to state whether the tonsils in a certain case are normal or abnormal. It is also impossible to give the boundaries of a normal tonsil. The anterior and posterior boundaries are fixed, being the pillars of the fauces, but the vertical extension cannot be definitely stated. Especially is this true of the lower border, prolongations of the tonsils extending in some cases as far as the laryngeal cavity. The amount of protrusion into the pharynx also varies greatly. And it is on this protrusion that judgment is generally based as to whether the tonsils are hypertrophied or not. This judgment is fallacious, because a tonsil that may be prominent from a lateral hypertrophy may be much smaller than one that is not seen, but which is greatly extended inferiorly. Arbitrarily, the pharyngeal limit has been fixed as a line on a level with the pillars of the fauces. I will not stop to comment on this, but only say that I think it erroneous. The point of commonality, as before stated, is the general structure of all tonsils, being masses of lymphoid tissue, showing on the outer surface numerous orifices, which lead down into blind pouches, and having the general appearance and formation of glands. The similarity, however, between a tonsil and a typical gland ceases with the general structure. For the function of a gland, in general, is one of secretion or excretion. But the normal tonsil neither secretes nor excretes. It was the supposition of its being a gland proper that led to the erroneous conceptions of its function. When it ceased to be considered as a gland, with excretory or secretory functions, investigators began to enquire along other lines. To Chiari of Vienna and Moure of Bordeaux we are indebted for much of the recent literature on this subject, and it seems to me their suggestions are worthy of consideration. The anatomical and histological structure of the tonsil proclaims it to be what? Simply a mass of lymphoid tissue. And what is the function of lymphoid tissue? Preeminently that of an absorbent. Here, then, are two conspicuous bodies on either side of the pharyngeal entrance, whose only function is that of absorbents. But with this idea there suddenly comes upon our consciousness a rather startling revelation. Not only laterally are there these two large absorbing bodies, but posteriorly there is another of identical structure which sends out connecting branches across the entire posterior wall of the pharynx; and also anteriorly, at the base of the tongue, is another mass of the same kind, which, with that posteriorly and laterally, forms a circle of lymphoid tissue, which almost completely encircles the entrance to the respiratory and alimentary tracts. This circle of lymphoid tissue is not there by accident. In the economy of nature it is there for some purpose. Lymphoid tissue, if not the home, is always the rendezvous of the leucocytes. They are there in countless numbers. The function of the leucocyte is manifold and wonderful. We understand but little concerning it, but the little that we do know is marvelous and astounding. The

*Read before the Illinois State Medical Society, Peoria, Ill., May 22, 1901.

phagocytic action is not the least. That proposition, I think, has been abundantly demonstrated.

You are all, doubtless, familiar with the theory. The throat is the great open gateway to the body. Through it pass all the essentials of life's sustenance. And through it also pass most, if not all, of the enemies of health, and the germs of death and disease. The food we eat, the water we drink, the air we breathe, pass this way. One does not have to stop to analyze this compound and intricate mass and volume to imagine the numerous pathological agencies that thus can gain entrance to our bodies. Nature has made an heroic effort to guard this vulnerable point. To use a military simile, she has placed four well-manned forts about this entrance in the form of the four tonsils, and has also thrown out far-reaching columns in the form of chains of lymph nodules, thus completely encircling this entranceway. I think there is no question that this is all for an important purpose, and we divine, at least, its reason. Throughout the earlier period of life, not much respect is paid as to what passes into the mouth or through the nostrils.

The tendency of the infant is to put into its mouth everything that comes its way. And on up through childhood it is pretty much the same. How many disease-producing microbes thus get into the mouth can only be imagined. And that these germs get in their work, we, as physicians, know too well. To limit the effect of all the inflammatory and infectious processes that involve the mouth and nasopharynx, nature has placed between this large field so easily infected and the deeper bodily structures her best defenders, namely, the four lymphoid structures and lymph nodules before mentioned, with their contained leucocytes. If one believes in the leucocyte, and especially in its phagocytic action, these lymphoid masses and nodules are a great preventive of many infectious processes.

I will not dwell longer on this part of my subject except to say that if what I have said is true, one will hesitate before thoughtlessly destroying this wall of defense.

Now, I know that the tonsils and the other lymphoid structures are subject to many inflammatory processes—many of them primary, but many also secondary. And I am familiar with the many arguments that are brought forth, attributing to these inflammations of the tonsils many secondary and remote pathological processes in other parts of the body. Much of this I am ready to admit. But the admission does not carry with it the confession that because the tonsils are subject to many inflammatory attacks, they are therefore useless and should be removed. It seems to me it is something like saying that because the thief enters our house by way of the door, because of a defective lock, we must therefore take out the door entirely. Now I imagine some of you say that by taking out the tonsil you not only remove the door, but at the same time fill in the door space with impassable material. But this is considering the tonsil itself as the only offending organ, and is forgetting altogether the rôle it plays as a guard against a deeper and more serious infection. Very many cases of tonsillitis are secondary; that is, reinfections, and the tonsils simply check a further extension of the infection, and in this case, instead of the tonsil being considered an enemy to the bodily good, it is a friend and benefactor.

With advancing years, and as the habits of the individual become more cleanly, there is less use for the tonsils, and they show a gradual retrograde process. And what are often very conspicuous bodies in childhood become almost unnoticeable in adult life.

I do not admit that simply because a tonsil projects into the pharynx beyond the level of the faucial pillars, it is hypertrophied. Neither do I admit that even if it is hypertrophied it is dangerously pathological. It seems to me the main question is, has it degenerated to the extent that it has lost its function, and having lost its function is it inimical to health? I would state unequivocally that a tonsil should not be excised simply because it projects beyond the faucial pillars, because such tonsil may possess all of its original function and perform a useful purpose. I also do not believe that simply because a child who has had one or two attacks of tonsillitis is seen upon inspection to possess slightly prominent tonsils, therefore the tonsils should be excised. Of course, to eradicate thoroughly such a tonsil would surely exclude the possibility of a future tonsillitis. But can one say that the tonsillitis is not the lesser of two evils, and that it was not in the effort to check a progressing infection that the tonsils bore the brunt of the onset and thus modified the infectious process to the extent that it localized itself in the tonsils and thus saved a more serious infection of a more vital organ? Let me suggest a few analogies. Suppose there is a venereal infection. We know if the initial lesion is not wholly localized or walled off by inflammatory exudate, we soon see the nearest efferent lymphoid structure become enlarged or hypertrophied in the effort to check the onward progress of the virus, and usually with success.

Or suppose a case of malignant growth; the same thing is seen. If the lymph glands (so-called) had not attempted to check the progress of the disease would not more distant and vital organs have become sooner affected? Looking then at the peculiarly arranged circle of lymphoid structures that almost completely encircle the pharyngeal entrance, is it not reasonable to suppose that it is there for a protecting purpose, and when without just cause one removes an important part of these protecting tissues, is one not doing an injury to the patient? Now, I believe that there are many justifiable causes for the excision of the tonsils, but that one of these is not simple tonsillar hypertrophy.

Before referring to some of the conditions which I regard as justifying excision of the tonsils, permit me to say just a few words regarding the pathology of tonsillitis. The error prevailed until a rather recent date regarding tonsillitis, as of many other diseases which exhibited some peculiar local manifestation, that the local process was the disease itself instead of being simply a local manifestation of a general and systemic infection; such, for instance, as the serous arthritis in inflammatory rheumatism or the membranous exudate in diphtheria. The inflamed joint and the membranous exudate were, for a long time, considered the disease itself. Now I think scarcely any one maintains that idea. And so the concomitant pathological processes that were often seen with these specific infections are not now considered as secondary infections (meaning thereby metastatic), but merely other local manifestations of the one general disease. In rheumatism the joint affection does not cause the endocarditis which so often accompanies it, but both are the result of the original specific infection. And so I believe that much that has been said regarding follicular tonsillitis as the cause of secondary infections, such as endocarditis or pleuritis, is based on a similar error regarding the pathology. Acute follicular tonsillitis is not merely a local in-

flammatory process confined to the tonsils but part of a general systemic infection.

Referring now to some of the conditions which justify the excision of the tonsils, I have time only to mention briefly the following:

1. A simple hypertrophy of the tonsils which causes them to occupy so much of the pharyngeal space as to prevent the entrance of sufficient air in breathing. But this would have to be considerable so as to cause the pharyngeal space to be of less caliber than the trachea.

2. In cases in which the hypertrophied tonsils have pressed on or drawn upon the pharyngeal opening of the Eustachian tube so as to close it or distort it and thereby interfere with its function.

3. Hypertrophied tonsils that are subject to recurring attacks of tonsillitis.

4. Tonsils that have previously been subject to recurring inflammations when the function of the organs has been destroyed and which show considerable degeneration.

5. Tonsils whose crypts have become filled with caseous matter which is offensive, conducing to foul breath.

6. Tonsils that are subject to lacunar ulcerations.

7. Cases that have developed a quinsy habit. In these cases the removal of the tonsil generally prevents a recurrence of the quinsy.

8. In cases of lupus or tuberculosis of the tonsil, as well as in cases of malignant growth.

9. When the enlarged tonsils interfere with voice production to the extent of annoyance or incapacity for continued speech, or where they interfere with the production of pure tones in voice culture.

10. After the age of puberty there sometimes remains a mass of more or less fibrous tissue, occupying the tonsillar spaces, which has lost most of its lymphoid characteristics and partakes of the nature of a foreign growth; when these are inimical to comfort or well being they should be removed.

I would like to speak of the differential diagnosis in some of the tonsillar affections, which I deem of great importance, but the limited time does not permit of my doing justice to the subject. However, there are a few suggestions that I beg to make regarding the common use of the term tonsillitis. Tonsillitis conveys no more meaning than the word fever. To say that a person has a fever means but little. The word only suggests a multiplicity of conditions, and one knows scarcely anything as to the real condition of the patient. While the word tonsillitis has not the complex and varied meaning of the word fever, still as it is generally used it may mean any one of many conditions. I will only briefly refer to the most important:

Acute Follicular Tonsillitis, more properly called croupous tonsillitis. The general characteristics of this affection you are all familiar with. Although the name would infer a purely local process, it causes a general systemic infection.

Herpetic Tonsillitis.—This is probably mistaken for follicular tonsillitis oftener than any other affection, and while it possesses much that might suggest the latter it is a radically different disease. As a rule, its onset is very rapid, the temperature quickly rising to from 103° to 105° F.; the headache is intense, chills are frequent, and there is considerable aching in the muscles and bones. As in follicular tonsillitis, during the first day or two it may be impossible to diagnose the condition. The throat symptoms generally manifest themselves about the second day, when the tonsils are seen to be red and swollen, as are also the pillars of the fauces and the pharynx. There soon appear numerous herpetic vesicles, more numerous on the tonsils, but also on the other parts of the pharynx, as well as the uvula. About the third day the vesicles have ruptured, small ulcers appear, which soon become covered with a whitish coating, a veritable false membrane, which may coalesce and cover the entire tonsil and also the posterior pharyngeal wall. The whole process disappears in four or five days, and convalescence is rapid. I have known these cases to be frequently called follicular tonsillitis, and they are doubtless also often called diphtheria. Herpetic tonsillitis occurs most frequently in malarious districts, and is believed to be caused by malarial infection. Be that as it may, quinine is the most efficacious remedy in these cases, and I believe that it is an error in diagnosis which is responsible for the statement often heard that quinine is a useful or even an abortive remedy in tonsillitis. A peculiarity of herpetic tonsillitis is, that it is not accompanied by glandular enlargement.

Ulcerative Lacunar Tonsillitis is sometimes mistaken for follicular tonsillitis, although this error should seldom be made, because the general course of the affection has but few points in common with follicular tonsillitis, although it can be more readily confused with some of the other diseases of the tonsils. Ulcerative lacunar tonsillitis exhibits but few initiatory symptoms, the first thing the patient notices being a difficulty in swallowing, and when an examination is made the lesion is present. There will be seen on one, sometimes on both, tonsils a grayish ulceration covered by a cheesy mass, which can be easily removed, leaving a deep red granular surface. While the borders of the ulcer are clean cut, red, and inflamed, but not much swollen, the rest of the tonsil is but little affected. The trouble is a purely local one, confined to one or a few of the crypts and not extending to the surrounding parts. The ulcer may be as large as a dime, or larger, and generally round or oval in shape. The ulcer may be quite deep, even extending to the floor of the tonsil. There is seldom any, or at most slight, fever. There is usually no swelling of the submaxillary glands. The lesion generally runs its course in a few days. If treatment is instituted it should be confined to mildly antiseptic washes.

The affections that have been mentioned are all promiscuously called tonsillitis, and yet how different are they in their essential characteristics as well as their treatment! I have refrained from mentioning diphtheria purposely, because my intention was to ask your consideration of the other affections of the tonsils rather than of the one of which you already know so much. But I wish briefly to mention diphtheria only for the purpose of saying a few words regarding the diagnosis from a bacteriological basis. It is simply this, that the presence of the Klebs-Loeffler bacillus in the throat of a person suffering from a tonsillar affection does not unequivocally stamp the case as one of diphtheria, and the judgment of the efficacy of a certain line of treatment based on such a diagnostic method is gravely at fault. Now I beg not to be misunderstood. I believe all cases of true diphtheria are caused by the Klebs-Loeffler bacillus, but every bacillus does not cause a case of diphtheria. In very many normal throats the bacilli have been found, but one would not say such persons have diphtheria, nor is it at all unreasonable to suppose that such a throat could have other inflammatory affections than diphtheria? We often find the pneumococcus in normal throats. Have such persons, therefore, pneumonia? Surely not. We often find in the intestines of healthy persons the typhoid bacillus. Have such persons, therefore, typhoid fever? Surely not. And so it seems to me that a diagnosis based on a bacteri-

ological finding only is most unreasonable. And yet I do not underestimate the great value of the bacteriological examination. I believe that every case of membranous sore throat of suspicious character should be most carefully examined, microscopically as well as otherwise, and if the Klebs-Loeffler bacillus is found, the case should be treated and guarded with extreme caution. It might be diphtheria, and until the question is completely settled one cannot be too careful. But the mere presence of the bacillus does not necessarily stamp the case as one of diphtheria. You might have a dynamite bomb in your house, but not necessarily an explosion. There may be an anarchist in your community and yet not anarchy. There may be an incendiary in a city, but not a conflagration.

As to the other numerous affections of the tonsils, such as tuberculosis, lupus, the various manifestations of syphilis, malignant growths, etc., etc., only one will be briefly mentioned, namely, mycosis of the tonsils. When this affection is present, we find on superficial examination what appears to be a yellowish or whitish deposit or exudate on the tonsils, and which might be mistaken for one or another of the various tonsillar affections. It is important to recognize the true nature of the trouble, because if improperly treated it runs a chronic course, and does not yield to the simpler methods of treating throat affections. The disease is characterized by the presence of the leptothrix buccalis—a fungous growth—and sometimes persists with great stubbornness. We may have to resort to a mechanical removal of the growth, but generally a cure can be effected by applications of chloride of zinc solution, 1 to 15, or tincture of iodine, or chromic acid.

A UNIQUE SPECIMEN OF VESICAL CALCULI.

By F. C. LARIMORE, M.D.
MT. VERNON, OHIO.

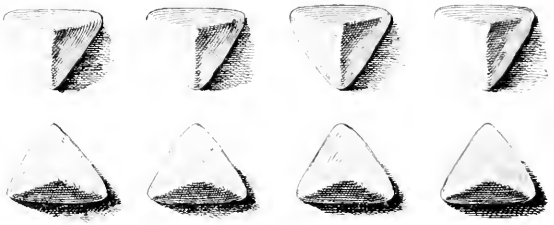
This case is regarded as worthy of report on account of the beauty, uniformity, and shape of the calculi. To the knowledge of the writer, the specimen has no rival in the collections of stones removed by the surgeons in Ohio, Baltimore, Philadelphia, and New York, the nearest approach being the celebrated jackstone calculi removed by Dr. Halsted several years since.

The stones, eight in number, uniform in size, tetrahedral in shape, hard, smooth, weighing one drachm each, were taken from the bladder of a physician. A section of one demonstrates that it was formed from a central nucleus, with concentric layers, each formed in the same way. When all the stones are matched together, a complete hemisphere is formed. I presume they assumed this relative position while in

the bladder, obeying the law of gravity, and always dependent with the changed position of the patient. The following history and report of operation shows that there was residual urine in the bladder for a long time. Hence the stones were always in a fluid medium. They were removed by a suprapubic cystotomy, with the patient in the Trendelenburg position; not by sight, but by the sense of touch, the index finger of the left hand guiding the forceps held in the right hand for seizing and removal.

The stones were all in one place in the bladder, like eggs in a bird's nest. Mounted on cardboard, the stones are seen to be so uniform, with four equal triangular surfaces, that the impression is at once created of their having been made in a mould. The following is the history of the case:

Dr. J. W. W., aged sixty-one years, began to have some trouble with his urinary organs in the spring of 1899. In the winter of 1900-1, he had to give up his practice on account of pain. In February, he passed a catheter, and removed one pint of residual



urine. He then continued to catheterize himself every three hours, with great comfort. From this time on he was unable to void his urine without the aid of a catheter. On February 28, 1901, I saw him first. He had emaciated and changed so much as to be unrecognizable. His bladder was irrigated with a half-strength Thiersch's solution, and sounded, when an audible click determined the presence of stone. The prostate gland was slightly enlarged. The urine was turbid, pale, alkaline, sp. gr. 1.005; it contained no sugar, but pus, bacteria, and a trace of albumin. The patient entered my private hospital March 2d, and was operated on March 7th.

I was assisted by Drs. J. E. Russell, L. W. Armentrout, P. Pickard, J. E. Lee, and Williams, a brother of the patient. The stones were removed by suprapubic cystotomy. The median lobe of the prostate, which was enlarged, was removed by enucleation with the fingernail and curette. A No. 35 rubber catheter was placed in the lower angle of the wound, and the bladder incision was closed down to the drainage tube with chromicized catgut, the skin and abdominal muscles being united with silkworm-gut. The drainage catheter was connected by glass with a piece of rubber tubing three feet long, the distal end of which was passed through a hole drilled in a cork stopper fitted into a graduated nursing bottle. The tubing almost touched the bottom of the bottle, in which one ounce of 1-100 carbol solution had been placed. The bottle was suspended by a string to the bed rail, the bottom swinging clear of the floor. The drainage was perfect. The nurse could record the amount of urine voided, empty the bottle, and recharge it with carbol solution without disturbing the attachments. The drainage tube was removed on the fourth day. The abdominal wound was completely healed on the fifteenth day. Convalescence was uneventful, and the patient was discharged April 7th with a good appetite and returning body-weight and strength. He writes me under date of July 24, 1901: "I am feeling quite well, have gained in flesh, weigh 143 pounds, and everybody says I look well; sleep well, eat well, and feel strong. I have some tenderness of the prostate, but it does not hurt me any to ride in the buggy. I cannot pass my urine without the catheter, which I have to use about every three or four hours. I often try to do without it, but cannot. I can pass it very readily. I think I am well of cystitis. The urine looks well and contains no mucus. I use Thiersch's solution about once a week now. I feel very thankful that I am as well as I am." The retention of urine is, no doubt, due to paralysis from over-distention of the bladder prior to the operation.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, September 14, 1901

THE ATTEMPTED ASSASSINATION OF PRESIDENT McKINLEY.

At seven minutes past four o'clock on the afternoon of September 6th, President McKinley, while receiving the people in the Temple of Music at the Pan-American Exposition, in Buffalo, was shot twice by an anarchist. The man had a pistol in his right hand, concealed by a handkerchief so arranged as to give the appearance of a bandage. He was in line with others passing before the President, and just as the latter was extending his hand, raised the pistol and fired two shots.

One bullet struck the sternum, and glanced off, producing simply a contusion, and was found in the clothing. The other one, which is thought to have been the first fired, penetrated the abdomen five inches below the nipple, and an inch and a half to the left of the median line.

Word was at once sent to the Emergency Hospital in the Exposition grounds, and Drs. Ellis, Mann, Jr., and Hall of the hospital staff bore the wounded President to the ambulance, and hurried with him to the hospital. This was at 4.14. On arrival at the hospital, the President was fully conscious. He was placed in one of the private rooms, but, on the arrival of Drs. Mann and Rixey, was transferred to the small operating room to the right of the entrance. At 5.07, just one hour after the shot, Dr. Matthew D. Mann arrived at the hospital, and Drs. Mynter and Parmenter arrived almost immediately. At half past five o'clock, Dr. Rixey of the U. S. Navy, the President's personal physician, arrived, and then the operation was begun by Dr. Mann, assisted by Drs. Mynter, Parmenter, and Lee. There were present also Drs. Wardin, Van Peyma, and C. G. Stockton. Dr. Charles McBurney of this city became subsequently associated with the case as consulting surgeon.

The abdomen was opened by an incision including the point of entrance of the bullet. It was found that the missile had penetrated the anterior wall of the stomach. This hole was immediately closed by a Lembert suture of fine silk, and then the organ was turned over, and a search was made for the point of exit in the posterior wall. This was quickly found, and sutured in the same way.

A careful examination showed that the intestine and other abdominal organs had not been injured. After a toilet of the peritoneum, the abdominal wound was closed without drainage. The further course of the bullet could not be traced, and the bullet itself was not found.

Shortly before the close of the operation, Dr. Roswell Park, who had been summoned from Niagara Falls, arrived at the hospital.

The illustrious patient stood the ether and the operation well, his pulse at its termination being 130, and of good quality. At half past seven he was removed in the ambulance to the residence of Mr. Milburn, where he is at the present writing.

For about twelve hours after the operation the temperature was in the neighborhood of 100°, and slowly rising; it then fluctuated between 101° and 102° for thirty-six hours, after which it very gradually declined. The pulse was 120 to 130, and the respiration about 25.

There have been at no time any symptoms of peritonitis or of septic poisoning.

The pistol used was, fortunately, one of slight penetrating power, and the bullet was of small caliber, otherwise the ball which struck the sternum would almost certainly have done far greater damage than that which perforated the stomach, even had it not caused instant death.

The great public interest manifested in the case made it necessary for the MEDICAL RECORD to send a member of its editorial staff to Buffalo to study it from its strictly scientific aspect. The data furnished by this gentleman can be considered, therefore, as thoroughly trustworthy, and based on authoritative statements of the different surgical attendants on the case. The idea was to obtain all the points of real interest from a surgical standpoint, and such as have been furnished can be considered strictly accurate.

A very remarkable feature of the operation was its performance so soon after the infliction of the injury, and in this respect it may be looked upon as unique. The details of the procedure could not have been better arranged if they had been planned beforehand. In fact, the ultimate success of the operation was largely due to this fortunate circumstance. This by no means detracts from the well-acknowledged skill of the operator and the perfection of all his details of modern technique. Fortunately, in consequence mainly of careful handling of the patient before the operation, only a very small amount of stomach contents escaped into the peritoneal cavity. Viewed by itself as a surgical procedure, it may be considered beyond criticism. No chances were taken for any failure of most minute details. In fact, it was the opportunity appropriately met of demonstrating to the public one of the many triumphs of modern surgery.

It is most gratifying to state that at the present writing the distinguished patient is on a fair way to complete recovery. The elevated temperature which for the first few days occasioned so much anxiety to the daily newspapers was largely due to the ordinary effects of secondary shock. Although general peritonitis was quite naturally feared, there was at no time any distinct evidence of such a complication.

During the first few days the stomach was kept quiet by rectal alimentation, and at no time was any nausea, tympanitis, or gaseous retention manifest. There was so little pain that no anodyne was required after the third day. Except for the fact that a portion of the bullet track in the course of the abdominal incision failed to unite—a trifling matter in itself—the case would not have had a

single drawback from a public sensational, or spectacular standpoint. The only trouble now from the latter view centers in the present uncertainty as to the location of the bullet. Although believed to be lodged in the muscles of the back somewhere in the lower dorsal or upper lumbar region, there has been no means as yet of proving such a point. Of course every hope now rests in the probability of the missile becoming safely encysted and consequently harmless. It is somewhat difficult to understand why, up to this writing, the x-ray, so easily and effectually applied, has not been brought into service. It would hardly be so much a matter of gratifying curiosity—as remarked by one of the eminent surgeons in the case—as of being absolutely sure of the terminal track of the missile. It is to be hoped that the bullet course behind and beyond the stomach is in a safely closed and aseptic condition. This would seemingly be the only absolute guarantee against any future trouble from secondary suppurating processes.

In calculating the naturally direct course of the missile from before backward to its supposed designation, it may be fair to assume that the only serious damage that was done was the double perforation of the stomach wall. Taking the chances of a shot in any other direction would have been more than hazardous. It seems quite evident, in the absence of any positive data to the contrary, that the general direction of the missile must have been in the mid-epigastric plane obliquely backward and to the left.

Such a course would explain the missing of the pancreas, and the splenic artery below, the coeliac axis internally, the spleen to the left, and the left suprarenal capsule and left kidney below. The escape of the liver was easily explained by the track of the ball being just external to the shelving top of the left lobe.

But whatever theories may be offered as to the precise nature of the injury, they can be very harmlessly ventilated in the face of the gratifying fact that the patient seems destined to recover and valiantly defy them all.

OPPORTUNITIES FOR MEDICAL RESEARCH IN AMERICA.

When one pauses to examine the currents in the stream of medical progress in this country, one cannot but see that in the drift of events research in experimental medicine is gradually assuming a more and more important position. The two factors that led to the growth of the present opportunities for research in pathology, bacteriology, and hygiene were the evolution of the American university from a mere "boarding school where the elements of the learned languages were taught to youths," as Mr Pattison, Rector of Lincoln College, once said of Oxford, to a seat of learning and research modeled after the German prototype, and the development of the old-fashioned American medical school, with its two years' curriculum of didactic lectures, into the modern type with four years of thorough training in laboratory and clinic.

Twenty-five years ago there was scarcely any provision for the pursuit of medical research in this country. The laboratory of the College of Physicians and Surgeons of Columbia University was established in 1878—twenty years after the appearance of the first edition of Virchow's *Cellularpathologie* and twenty-eight years after the discovery by Davaine of the first important pathogenic germ—that of anthrax. The Carnegie Laboratory of the Bellevue Hospital Medical College was opened in 1885; the Loomis Laboratory of the New York University (now of Cornell University) in 1886; the Hoagland Laboratory in Brooklyn in 1888, and the Johns Hopkins Hospital Laboratory in 1889. The corner-stones of the other pathological laboratories throughout the country for the most part bear later dates.

To-day there is scarcely a second-rate medical school in these States that does not provide some opportunities for medical research. At Johns Hopkins, Columbia, Harvard, Pennsylvania, Chicago, and some of the other universities there are scholarships and fellowships open to qualified workers in pathology and allied themes. At each of these institutions, there are on the average from three to five such fellowships. Thus, for example, there are at Columbia the three fellowships of the Alumni Association, the Alonzo Clark scholarship and the Maria McLean Proudfit fellowship, five in all. The number of leading laboratories in which such fellowships and scholarships are maintained may be estimated to be, at the highest, ten; so that there are at present about forty men in this country who receive incomes for research in medicine.

The recently organized Rockefeller Institute for Medical Research will make possible the appointment of about forty additional men; in other words, will double the number of men engaged in this work in America who are paid salaries and who are not necessarily occupied in teaching.

The plan of work of the Rockefeller Institute excludes, for the present, any expenditure for a building, though the ultimate desirability of a central laboratory is not ignored by the Board of Directors. In this, we fancy, the directors are following the advice of Huxley as given in his address at the opening of Johns Hopkins University, September 12, 1876: "It has been my fate to see great educational funds fossilize into mere brick and mortar in the petrifying springs of architecture, with nothing left to work the institution they were intended to support."

Mr. Rockefeller placed at the disposal of the directors two hundred thousand dollars, of which the sum of twenty thousand is to be expended annually. It is understood that the gift will be increased as the demands of the work grow. This money is to be divided, according to the present plans of the Board of Directors, into sums averaging about five hundred dollars each, which shall be paid annually to the holders of the scholarships or fellowships established by the institute. In special cases, the salaries will be made larger, but in others the remuneration may be less than the average. The appointments are to be made in each case for one year only, although reappointment for another year will probably be given to such men as require more time for the completion of their work. The candidates will be recommended to the Board of Directors by the heads of the various laboratories, and from the list thus formed the directors will make their selections. Each candidate must be certified as to his qualifications, especially as to

his ability to carry on the research undertaken, and must be pursuing or about to pursue an investigation on some important subject in pathology, bacteriology, or hygiene.

It is evident that this plan is in every way calculated to secure the object of Mr. Rockefeller's gift. Yet, in one respect, we should venture to suggest a change, namely, as regards the salaries paid to these workers. Five hundred dollars may be a bait to the recent graduate, but one cannot expect a man of maturer years and increased financial needs to give most of his time for so small an annual income. While a certain number of beginners in pathological research may be admitted to these scholarships, it would certainly be advisable, if not necessary, for the attainment of results of the greatest value, that men of experience who have already made their mark in science be attracted toward this corps of investigators by salaries representing a modest, but sufficient competence. It must not be forgotten that the attention paid to the results of an investigation by the scientific world is directly in proportion to the amount and value of the investigator's previous work, and that the weight of his conclusions depends upon the same factor.

Again, if the appointments are made for one year only, the personnel of this body of workers will constantly change. What advancement in the ranks of his fellows will be open to the scholar who has completed an investigation on a difficult and unexplored question, and what will become of him after his term of scholarship is at an end? Every one of the forty or more Rockefeller scholars cannot obtain an academic appointment at the end of his year of scholarship—there are too few vacancies in the universities for that. It would seem better to arrange for a system of grades with increasing salaries in which promotion will be secured by length of service and value of work done, for in this manner there would be a survival of the fittest, the lower ranks changing from year to year, the upper being filled by scientific men of the highest type. The Rockefeller scholars would then not be in the position of our army contract surgeons, who have nothing to look forward to except an honorable discharge, promotion or pension being out of the question. The institute would rather support a body of men who could devote themselves entirely to research, and who would not be obliged to teach or to do other work to make both ends meet. A good teacher is not always a good investigator, and one who is unsurpassed in research may not be able with success to impart his knowledge to others. In such cases the universities might contend among themselves for the honor of having a Rockefeller research scholar on their academic staff. In this way the institute will become a nursery for both teachers and investigators and its fellowships will be steps to the highest academic honors.

THE VULNERABILITY OF THE APICES OF THE LUNGS TO TUBERCULOSIS.

Although it is generally recognized that the apices of the lungs are peculiarly susceptible to tuberculosis, and the right more so than the left—there is no agreement as to the cause for this predilection. According to the most commonly accepted view, the comparative immobility of the upper portion of the chest, with diminished functional activity on the part of the apices, is the responsible factor, but neither this nor its modifications or substitutes are entirely satisfactory. According to an explanation proposed by Drs. E. H. Colbeck and Eric Pritchard (*Lancet*, June 8, 1901), the movements of the apices of the lungs, when not properly supported by the soft parts and the external extremities of the clavicles become inverted—being sucked in during inspiration and bulged out during expiration. At the junction of the tissues thus affected, with those undergoing normal respiratory movement, is an area of minimum activity, and it is especially here that foreign bodies, including tubercle bacilli, find lodgment and set up irritation; and this corresponds with the usual primary seat of pulmonary tuberculosis. The apex of the right lung is more commonly and more early the seat of tuberculosis because it projects higher into the supra-clavicular space and is even less well supported than the left. The theory thus briefly outlined is not without practical bearing, inasmuch as in conformity therewith, development of the muscles of the shoulder-girdle by means of tree-climbing, ball-throwing, horizontal ladder and bar exercises, or any systematic muscular training that brings into activity the great pectoral muscles is indicated as both a prophylactic and a therapeutic measure.

ARTERIAL HYPERTONUS.

By arterial sclerosis is meant a condition of fibrous hyperplasia, with diminished elasticity of the coats of the arteries, particularly those of smaller size. There has been some difference of opinion as to whether the morbid process begins in the middle or the internal coat, but in any event it is generally believed that it is the latter that especially suffers. The process may exceptionally be localized to a circumscribed area, but almost invariably it is general in distribution. It is probably dependent upon the presence of irritants in the circulation, acting directly upon the coats of the vessels and indirectly through a like deleterious influence upon the vasa vasorum. As a secondary result, degenerative fibroid changes take place in the viscera and the tissues generally and in this way physiological senescence and eventual dissolution are brought about. Atheroma, on the other hand, is generally considered a condition of fatty degeneration of the intima of the arteries, with necrosis and ulceration, and which may secondarily be followed by deposition of calcareous matter. In addition to the two morbid processes mentioned, Dr. Wm. Russell (*Lancet*, June 1, 1901) describes a third, which he designates arterial hypertonus and which may occur independently or be associated with the others. In the presence of this condition the normal arterial tone is increased, and the vascular tension may be heightened, with a reduction in lumen and a diminution in the blood-carrying capacity of the vessel, as a result of contraction of the circular muscular fibers of the walls of the arteries. This modification may be detected by a trained and sensitive finger, but it can be more distinctly demonstrated by means of the sphygmograph and the arteriometer. With the aid of the former it can be shown that the artery is in a state of contraction, the swing of the lever being less, the percussion-

stroke is shorter and less abrupt, the summit tending to be more rounded and the predicrotic notch less evident, while the arteriometer measures the diameter of the vessel. Arterial hypertonus may occur under many different conditions, probably as a result of the action of toxic substances introduced from without or generated within the body. In the young and the robust it is associated with heightened blood-pressure and a pulse of high tension, while in the aged and the debilitated when the heart is feeble, it may cause lowering of the blood-pressure and heart failure.

If long continued or frequently repeated, arterial hypertonus is likely to be followed by hypertrophy of the muscular walls of the vessel, while the presence of irritants in the blood gives rise to hyperplasia of the subendothelial connective tissue of the intima. The treatment of the condition consists, apart from correction and avoidance, so far as possible, of the etiological factors, in the administration of remedies capable of relaxing muscular spasm, such as the nitrites, with which the iodides, in small doses, may be serviceably conjoined.

News of the Week.

Examinations for the Army Medical Department.—The examination of applicants for appointment as Assistant Surgeon in the Army has been resumed in Washington and San Francisco; the Army Medical Boards convened in these cities will remain in session so long as there are candidates to be examined. Seventy-six vacancies in the Medical Department still remain to be filled, and as it is desired by the military authorities that the Department be filled up to its full legal limit as early as practicable, all eligible applicants will be afforded opportunity for examination; those found qualified will be commissioned at an early date. Information as to eligibility, nature, and scope of examination, etc., may be obtained upon application to the Surgeon General, U. S. Army, Washington, D. C.

Dr. Calmette's Personal Experience with Antivenene.—Dr. Calmette, director of the Lille Pasteur Institute and discoverer of the snake-bite serum, was engaged, one day last month, in extracting venom from the poison fangs of snakes, when one of the reptiles bit him. He immediately gave himself a hypodermic injection of antivenene, which he had himself prepared, and which he had been using in experiments upon animals, with most happy results. The arm swelled a little, and the experimenter had a slight fever, but no other symptoms appeared, and recovery promptly followed.

The Omega Upsilon Phi.—The Fifth Annual Convention of the Omega Upsilon Phi Fraternity Medicale was held August 29th and 30th at Buffalo, N. Y. Dr. Edward M. Thompson of New York City was elected President, Dr. Dean O. Thompson of Hornellsville, N. Y., Secretary, and Dr. George H. Minard of Lockport, N. Y., Treasurer. A banquet was held at the Hotel Genesee on the evening of August 29th. The next Convention will be held in New York City during September of next year.

The Winnipeg Meeting of the Canadian Medical Association, a special report of which appears in this issue, will go down in the annals of that association, our correspondent writes, as the best meeting hitherto held. The number of members registered was 175, a number considerably larger than that at Ottawa last year, and second to that of the meeting at Toronto in 1899. A large number of new members was elected, particularly from Ontario, Manitoba, the Northwest Territories, and British Columbia. Every province was represented at the association meeting, with the single exception of Prince Edward Island, one delegate coming as far as from North Sydney, Cape Breton. The meeting was generally voted a pronounced success; and certainly the profession in Winnipeg and Manitoba and the citizens of Winnipeg more than eclipsed in point of social functions any previous meeting. One of the most important discussions took place on the formation of a Medical Defence Union; and it is very gratifying to have to record that such an organization was unanimously supported by the association. All the leading officers of this protective association are located in Ottawa, and Dr. Russell Thomas of Lennoxville, P. Q., and W. S. Muir of Truro, N. S., are deserving of much praise for the great, good work they have performed in this connection. Much regret was expressed at the resignation of the General Secretary, Dr. F. N. G. Starr of Toronto, who has so long and so ably discharged the responsible and important duties of this position.

American Association for the Advancement of Science.—At the recent meeting of this association, in Denver, the following officers were elected: *President*, Professor Asaph Hall, U. S. N., retired, professor of astronomy at Harvard University; *Permanent Secretary*, L. O. Howard, chief entomologist Agricultural Department, Washington; *Assistant Permanent Secretary*, Richard Clifton, Agricultural Department, Washington; *General Secretary*, D. T. MacDougal, director of the laboratories, New York Botanical Gardens; *Secretary of Council*, Professor H. B. Ward of the University of Nebraska; *Treasurer*, Professor R. S. Woodward, Columbia University, New York City. The next meeting will be held at Pittsburg, June 28-July 3, 1902.

The "Journal of Medical Research" is a new publication, succeeding the *Journal of the Boston Society of Medical Sciences*, to be devoted to the publication of original investigations in medicine. The numbers will be issued at intervals as material accumulates, each part containing fifty or more pages. The journal, which is under the editorial management of Dr. Harold C. Ernst, who also edited its predecessor, will publish the proceedings of the American Association of Pathologists and Bacteriologists, the Boston Society of Medical Sciences, and other scientific bodies. The first number contains most of the papers read at the annual meeting of the American Association of Pathologists and Bacteriologists in April, 1901.

Suit against a Christian Scientist.—A suit for $6,000 damages in which malpractice (or is it malpense?) is alleged, and in which Irving C. Tomlinson, first reader in the Christian Science Church at Concord, N. H., is the defendant, has been brought by a woman who alleges that she accepted treatment for appendicitis, and that she did not receive common skill and care. The case has been in the docket of the Supreme Court for some time, but a hearing has been postponed on account of illness.

Gift to the Newport Hospital.—It is announced that Mrs. Cornelius Vanderbilt will erect a new building for the Newport (R. I.) Hospital as a memorial to her late husband. Plans for the building are being prepared, and work will be begun as soon as possible. The building will be at the east end of the hospital grounds, near Powell Avenue. There will be two stories, the upper one to be used for private rooms and the lower one for the out-patient depart-

ment, which has been very successfully operated, as far as accommodations would permit, for some time. The building will be constructed of the same materials and on the same general plan as the buildings already in existence, except that it will be a two instead of a one-story structure.

Army Hospital Corps Men as Nurses for the President.—The male nurses in attendance on the President are men of the United States Army Hospital Corps, who were detailed for this duty immediately after the shooting of the President, from the detachment of the Hospital Corps men on duty with the field hospital exhibit of the Army Medical Department at the Pan-American Exposition. The men selected for this duty were Acting Hospital Steward Palmer A. Eliot and Privates Ernest Vollmeyer and John Hodgins. All of these men have completed the course of instruction at the school for Hospital Corps men at the Army General Hospital at Washington Barracks, D. C., beside which Steward Eliot is a graduate of the Bellevue Hospital training school for nurses, and Private Vollmeyer is a graduate nurse of the Presbyterian Hospital of New York City. Private Hodgins is a soldier of nine years' service in the army and long experience in military hospitals. Much of the attention required in the President's care is of such nature as cannot be performed by the female nurses in attendance, and the efficiency of these men is such as to have elicited much favorable comment from the staff of attending surgeons. Army medical officers are much gratified that the Hospital Corps should be officially connected with the President's case, and have the opportunity of so publicly demonstrating its professional efficiency and the excellence of its personnel.

A Law against Substitution.—Tennessee, as we understand, is the only State in which there is a special law against the substitution by pharmacists in filling physicians' prescriptions of any drug by another not called for in the prescription. This law, as published in the *Southern Practitioner*, is as follows: "Section 1. Be it enacted by the General Assembly of the State of Tennessee, That it shall be unlawful for any corporation, firm, or person, or any combination or association of corporations, firms, or persons engaged in the business of buying, compounding, and selling drugs and medicines, to substitute any drug or medicine in lieu or instead of that given to the patient by the physician on the face of his prescription. Section 2. Be it further enacted, That it shall be unlawful for any agent or employe of such person, firm, or corporation or association or combination of persons, firms, or corporations engaged in the business of buying and selling drugs in this State, to substitute any medicine for the specific medicine mentioned in the physician's prescription. Section 3. Be it further enacted, That any person, firm, or corporation violating the provisions of this act, or aiding or abetting the violations of the same shall be guilty of a misdemeanor and upon conviction shall be fined not less than $25 nor more than $100 for each and every offense. Section 4. Be it further enacted That this act take effect from and after its passage, the public welfare requiring it." This act was approved in April of the present year.

Malaria Imported from Italy.—In the annual report of the Massachusetts State Board of Health Dr. S. W. Abbott has much to say of malaria in various parts of the State, which he believes to be an imported disease. During the past ten years, he says, every case of malaria investigated in Massachusetts has been traced to the presence in the neighborhood of Italian laborers. He discusses in particular the prevalence of the disease along the shores of the Sudbury and Concord rivers, and especially in the towns of Concord and Billerica. In both these places malaria was apparently introduced by Italian laborers engaged in digging up the roads during the construction of the water-supply and sewerage systems. In Ipswich malaria had occurred in four houses, its appearance in each instance coinciding with the presence of Italian laborers who were working in the vicinity and who came repeatedly to the houses for water.

The Duchess and the Bone-setter.—At a recent garden-party entertainment for the benefit of crippled children in London, the Duchess of Sutherland paraded the grounds with "an eminent bone-setter," who is said to have attended Her Grace on various occasions. Current professional comment was that if the Duchess chose to trust her limbs to a quack she could do so; but if, as was generally believed, she wished to place the crippled children under his care she should be plainly told to confine the results of her folly to her own. The curious inconsistency of the British medical law is shown in the fact that this ignorant man is permitted to practise surgery without molestation.

The Medical Examination of Japanese at Honolulu.—In reply to Japan's remonstrance against the treatment accorded Japanese by the medical inspectors at Hawaii, this country is reported to have promised to investigate the matter and to adopt suitable measures to prevent a recurrence of the complaint.

A Just Fate.—A feminine faith-cure devotee of Urbana, Ohio, is reported to have run against the hard facts of nature. She attempted to cure four cases of smallpox occurring in one family, and not only failed in that, but contracted the disease herself. She then sent for a physician and "took her medicine" in great humility.—*Cleveland Journal of Medicine.*

A New Law Regarding Wet Nurses in Paris.—The Prefect of Police in Paris recently issued an order that wet nurses must not leave their own infants to be bottle fed, but must see to it that they, too, are wholly or in great part nourished at the breast. This has caused a great scarcity of wet nurses, and the Parisian mothers are in despair at having to choose between suckling their own offspring and bringing them up on the bottle.

Opposition to the Cigarette in Scotland.—A petition, signed by two hundred physicians of Edinburgh and Leith, has been sent to Parliament praying for the enactment of a law forbidding the sale of tobacco to children under sixteen years of age. The document is directed mainly against the use of cigarettes by boys.

Meeting of Hospital Superintendents.—The third annual conference of the Association of Hospital Superintendents was held on Tuesday, Wednesday, and Thursday of this week at the Murray Hill Hotel, in this city. The officers serving at this meeting were: Charles S. Howell, Superintendent of the Western Pennsylvania Hospital, Pittsburg, chairman; Dr. Frank E. Baker, Superintendent of the City Hospital, Newark, vice-chairman; James S. Knowles of Cleveland, Ohio, Secretary, and A. W. Shaw, Superintendent of Harper Hospital, Detroit, Treasurer.

Gifts to Philadelphia Hospitals.—John D. Lankenau, the well-known philanthropist and member of the Drexel family, who died two weeks ago, left upward of $1,500,000 to be divided equally between

the Graduate Hospital of Philadelphia, and the Mary J. Drexel Home for Aged Women. He was President of the Board of Trustees of the German Hospital, and was the founder of the Drexel Home.

The Lane Medical Lectures at San Francisco were delivered this year, on September 2d-6th, by Mr. Malcolm Morris of London, editor of the *Practitioner*. The subject of the lectures was the "Pathology of the Skin in Relation to Certain Social Problems."

Food Poisoning. One hundred and forty men of the Twenty-seventh Regular Infantry at Fort McPherson were taken suddenly ill with the symptoms of ptomain poisoning one day last week. All were affected in the same way with cramps, high fever, headache, and extreme restlessness. About the same time, ninety persons who ate clams at a lunch given at the opening of a new public building in Cleveland were also suffering from ptomain poisoning. All were made quite ill, but none died.

Condemnation of a Jersey City Hospital.—Dr. John D. McGill, President of the Jersey City Board of Health, has reported that the City Hospital in Baldwin Avenue is infected with disease germs, and should be burned. The roof leaks badly, the sanitary conditions are bad, and the building is alive with vermin. It is said that nurses are sometimes obliged to move cots in the men's ward to the middle of the room to prevent patients from getting soaked with rain which leaks through the roof.

Additional Accommodation for Smallpox Patients.—At a recent meeting of the New York City Board of Health bids were opened for the erection of two additional pavilions for the accommodation of smallpox patients on North Brother Island. Four bids were received, ranging from $21,000 to $17,000, the firm making this lowest bid being awarded the contract. The pavilions are to be wooden structures, about 100 feet by 50 feet, and are to be one story high. Each one will accommodate thirty patients.

The Plague. Two men died from this disease in Rio de Janeiro on September 5th. They were employees in a newspaper office.

The King of England is reported by a London paper to be suffering from cardiac trouble. The journal asserts that though he "is conscientiously submitting to the light, water, and massage 'cure' at Homburg, his heart trouble, from which he has suffered since and before his accession, shows no improvement."

Obituary Notes.—Dr. Gates B. Bullard, one of the best-known physicians in Northern New England, died at his home in St. Johnsbury, Vt., on September 4th, aged seventy-two years. He was a graduate of the Dartmouth, N. H., Medical College in the class of 1855. He was surgeon of the Fifteenth Vermont Regiment in the Civil War, and later Surgeon General of Vermont. He had served in both branches of the legislature and as a Commissioner for the Insane.

A Case of Malarial Remittent Fever Treated with Large Doses of Arsenic. C. J. Gremillion reports a case of malarial remittent fever in a woman who exhibited a marked idiosyncrasy to quinine, that drug producing severe pain in the stomach, cramps in the legs, cold, clammy perspiration, and rapid, labored respiration. She received five drops of Fowler's solution for three days every four hours, then every hour for two days, then every two hours for twelve hours, and afterward ten drops three times a day. She made an uneventful recovery. The case is interesting because of the idiosyncrasy to quinine, and on account of the quantity of arsenic taken without symptoms of poisoning. *New Orleans Medical and Surgical Journal.*

THE PROBABLE COURSE OF THE BALL IN PRESIDENT MCKINLEY'S CASE.

In view of the great public interest in the case of President McKinley, and in the absence, up to the present writing, of any definite demonstration of the exact course of the bullet, the MEDICAL RECORD presents a study of probabilities which, from anatomical and surgical standpoints, may prove interesting to our readers. The accompanying illustrations have been made with great care, and with special reference to their particular adaptability to the purposes of the article. Figs. 1 and 2 indicate the points of entrance of the missile from the front, and Fig. 3 shows, in a schematic way, the relation of the important internal organs in an anteroposterior section of the trunk.

At best, no absolute theory can be advanced as

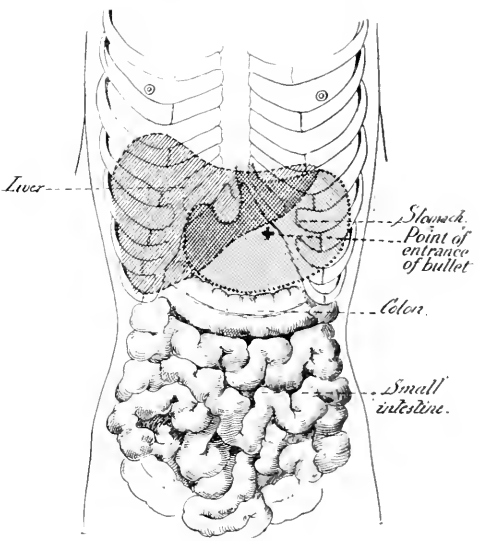


Fig.

to the direction of the ball, as the latter has not been traced beyond its point of exit from the posterior wall of the stomach. Nor can any positive information be obtained as to the relative positions of the would-be assassin and his victim. It was evidently intended that the pistol should be fired point blank, the parties nearly facing each other, and that the heart should be struck. In the absence of any proof to the contrary, it must be assumed that the aim was really in a direction from before backward, slightly to the left, and on a horizontal plane.

In the present aspect of the case, considering the important organs in the region of the wound tract, the great wonder is that so many of them escaped mortal injury.

The opinion of the surgeons in attendance on the President is to the effect that the foreign body is lodged in the muscles of the back somewhere in the region of the eleventh intercostal space and possibly in the substance of erector spinæ muscles. This would give the ball almost a horizontal direction from before backward. It is impossible to believe that it took a more internal course toward the vertebral column, as the cœliac axis

or even the aorta itself would undoubtedly have been wounded. It has been quite clearly demonstrated by the operation that the stomach was the only important organ injured. The left edge of the liver escaped harm by the merest chance of its position and thus a most formidable if not a fatal complication was averted. There was no injury to the adjacent cartilage of the eighth rib.

In placing the point of exit of the ball on a line with that of its entrance as in Fig. 2, the relative positions of the internal organs in the neighborhood can be easily studied. The only apparent reason why all these important parts escaped injury is on the supposition that the real course of the missile is thus properly placed in the diagram mentioned. Toward the median line are the important blood vessels already named. Inferiorly are the splenic vein and artery, the pancreas, and the left suprarenal capsule and kidney, and posteriorly and externally the spleen. The only point for the safe transit of a bullet would be seemingly in a very limited space within these boundaries.

The operator has given the best of reasons for not probing too much for the lost bullet, as such a course, considering the proximity of important blood vessels, would have been extremely hazardous. Considering also the necessity of shortening the period of shock as much as possible, there was no time for deliberate dissection or prolonged search. Besides it is quite usual under the circumstances for the course of a ball to be lost when it is continued through the loose areolar and fatty tissue usually found in the neighborhood of the parts involved in the operation. It was not impossible for the missile after its escape through the posterior wall of the stomach to drop into the peritoneal cavity.

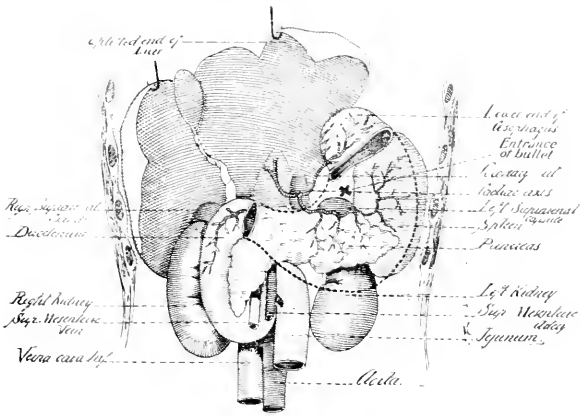

Fig. 2.

If such had been the case, however the ball would have been easily found by the surgeons during their careful toilet of the peritoneum. If by any chance the ball had escaped detection in that situation there would have been a very prompt clinical evidence of the fact.

If the ball be actually lodged in the muscles of the back it could not be more favorably situated for fulfilling the conditions of encystment nor be more out of the way for resisting the effects of ordinary pressure irritation.

GEORGE F. SHRADY, M.D.

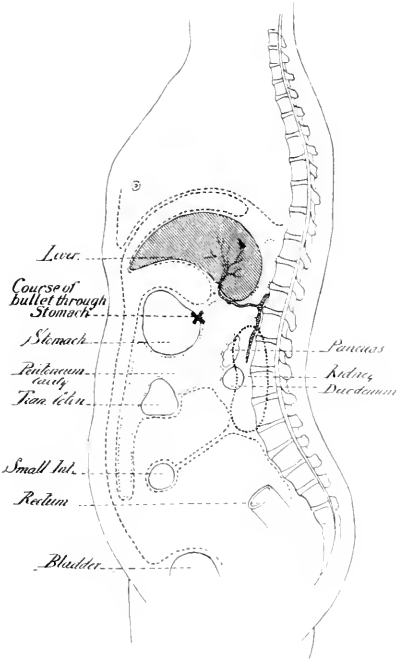

Fig.

Malignant Neoplasms.—D. M. Currier believes that every symptom of cancer and every characteristic of its many forms are in strict harmony with the parasitical theory of the disease, and can be more readily and rationally explained under this theory than any other. Eiser claims to have discovered an amœba in cancer, for which the name Cancriamœba macroglossa is suggested. The author describes its properties and method of action. As to treatment, the *general* treatment is to aid the local to check the disease and to keep it in a dormant condition for the rest of life. For these purposes phosphates should be given liberally, and thyroid extract. Sulphur is the laxative to be given, opium is better for the relief of pain than opium. As to local treatment, cataphoresis is opening up a field of vast possibilities. Arsenious acid is excellent in some cases. Chloride of chromium should be used in case of scirrhus situated deep in the cellular tissue with the skin intact. Salicylic acid, lactic acid, and formalin, all have their uses. Eucaine or cocaine should be applied locally when the pain is severe.—*Annals of Gynæcology and Pediatry.*

The Surgical Treatment of Varices and Varicose Ulcers of the Lower Limbs.—Alfonso Nardi reviews the various methods of operating for this affection, and concludes by saying that no one of them can be said always to produce the desired effect, while each will give satisfactory results under certain circumstances. The physician must judge in individual cases which is the better operation to choose and not be bound by prejudice or partisanship to any special method. The earlier any form of treatment is applied the better the chances of cure.—*La Riforma Medica.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LAUNDRIES AND FACTORIES ACT—CONTAMINATED FOOD—EPIDEMICS—JURYMEN ON HOSPITAL CASES—DIRECTOR-GENERALSHIP—THE TROPICAL EXPEDITIONS—BEQUEST TO HOSPITALS—RECENT DEATHS.

LONDON, August 23, 1901.

In order to carry the factory bill on which much labor and time had been expended the government abandoned the clause relating to laundries at the last moment. It seems unfortunate that opposition should be made to so useful a measure of protection of public health. But certain religious communities and philanthropic associations conduct laundries and some of them greatly object to inspection. The Irish members accordingly took up the cry that the clause was intended to apply to conventual laundries and that inspection of them was unnecessary and would be an outrage on their good work. The end of the session was so near that the threat to use every form of opposition sufficed to make the government omit the clause. From a public health point of view laundries surely should be brought under proper supervision and conducted in a manner similar to that employed in disinfecting establishments.

The close of the parliamentary session liberates a good deal of space in the newspapers so that many topics come to the fore—among them those which touch hygiene. Quite a commotion has been just raised by statements as to the contamination of our foods, apart from wilful adulteration. Milk, fish, and other foods are particularly liable to absorb noxious matters. Some time ago I mentioned that typhoid was reported to have been traced to a cooked-fish shop, but the evidence was not conclusive. Now the outcry raised has been directed against fish exposed for sale in the shops which are kept completely open for the sake of ventilation. To close them in hot weather would certainly be worse. Some one related that having bought some fine fish in the Strand, he found, after it had been cooked and served at table, it had a peculiar tarry flavor. This he attributed to the fact that the Strand was being repaired. For some time that thoroughfare has been "up"—indeed that is almost its chronic condition—what with telephones, gas, water, and other authorities who never seem to act together. It is not impossible that the tarry-fish story is due to the pen of a press gentleman who works in the Strand or to some one who is intent on putting down the costermonger rather than assailing the shopkeeper. Be that as it may, there is no doubt that our food is liable to contaminations more disgusting and dangerous than tar. The clouds of horrible-smelling dust that are distributed by some of the dust carts ought to engage the attention of the local sanitary authorities. The sweeping machines, too, are sometimes employed without previous watering of the roads, and offensive distributors of disease-bearing dust they then become. Both these sources of danger could be reduced to a minimum by adequate supervision, and some of us are hoping that our new municipalities may be more active in such ways than the superseded vestries.

Glasgow has now got rid of the epidemic of smallpox. There were 1,850 cases during its prevalence and 230 of them were fatal. The money so freely spent by the corporation on vaccination and re-vaccination was clearly a good investment under the circumstances, but the citizens may well reflect that they would have been saved much had they not neglected the preventive.

Belfast is suffering from a serious epidemic of typhoid fever. The notifications in the past month reached 306 and the cases were widely distributed over the city. The deaths were 167. The public health committee are roused to the danger and propose to deal effectually with the sanitary reforms required. Foremost seems to be a new water supply. With this a more efficient system of drainage is necessary. No doubt the many artisans' dwellings, which are constantly on the increase, add to the difficulties of the situation, but Belfast has found out that she must stir herself and put her sanitary system on a better footing.

There is also a rather severe outbreak of typhoid at Rounds near Northampton. Three deaths have occurred and ninety cases have been reported in the last fortnight, so that more deaths may be expected to follow. The outbreak seems to have been traced to a well from which 200 families were supplied, but how it got polluted does not yet appear. The authorities appear to be energetic. Private houses are being converted into isolation hospitals, and extra nurses are engaged to take charge of the patients. The rate-payers are organizing to prevent a lavish expenditure, as they are already burdened with a rate of more than one-third of their assessed rental. But while protesting against extravagance in the panic, they will not oppose measures of precaution if economy is practised.

Juries often pretend to decide what doctors ought to do or not to do in certain cases. They have not seldom censured a doctor who has made a post mortem without the authority of friends or the coroner. At an inquest on Monday on a child aged three who was run over and killed, the opposite view seems to have prevailed. Dr Louisa G. Anderson, resident surgeon at the Royal Free Hospital, said she saw the child was dead and did not make further examination, as she expected a post mortem would be ordered. Pressed by the coroner as to whether she should not have examined as to the injuries received she said, no—she waited for the authority to make a post mortem and determine thereby the exact cause of death. As the wheels of the van passed over the child, she was asked if that caused death, and answered, undoubtedly. Then, said the coroner, the injuries would be internal? That, replied witness, is hypothesis. Do you not think the injuries must have been internal from crushing? I think it probable. Then the immediate cause of death was shock and collapse? I imagine death was probably due to shock. Yes, said the coroner, that will do, and then charged his jury to the intent that Mrs Anderson expected an order to perform a post mortem; otherwise she would have, no doubt, made a closer examination, as the jury had suggested should have been done. On which a juryman said: "It seems to me when a child arrives dead they take no further notice of it." Now if Mrs. Anderson had made an autopsy, without the order of the coroner, he would have declined to pay a fee and we should have had the jury and probably the friends raising an outcry against such a proceeding. Juries often seem to desire to find fault with the doctor and Mrs Anderson was quite right to make no autopsy without the coroner's order.

Sir F R Cruise, a past president of the Royal College of Physicians in Ireland, succeeds the late Dr. William Moore as one of the physicians-in-ordinary to the King.

Surgeon-General Jameson, C.B., is to have an increase to the pension proposed to give him on retiring. Perhaps this is a proof that the recent demonstration of the profession was noted by the War Office and is admitted as a proof of the value of his work as Director-General. It would have been more graceful if a step in his order had been added.

After much delay and mystification, it is announced that Dr. W. Taylor, Chief of the Indian Medical Department, is to come home and take the vacant post of Director-General. He will arrive in four or five weeks and will have to complete the reorganization of the R. A. M. C.

Dr. W. Hanna has been appointed Assistant Medical Officer to the Port of Liverpool. He has done three years' plague duty in Bombay, where he also worked in the Government Research Laboratory.

Major Ronald Ross, F.R.S., is on his way home again from the West Coast of Africa. He has visited Gambia, Sierra Leone, the Gold Coast and Lagos, and is now returning in order to arrange for the despatch of a further expedition.

Dr. Daniels of the London Tropical School is on the way to Sierra Leone. It is probable that the next expedition—the seventh from Liverpool—will leave that port within the next week or two.

Mr. A. J. Dettmar, who died on July 25th last, aged fifty-eight, has left a large sum for the benefit of some of the London hospitals. His trustees are to distribute £1,000 a year for fifteen years in such proportions as they think fit among the National Hospital for Paralysis, the Hospital for Epilepsy and Nervous Diseases, and St Mary's Hospital. A sum to produce £1,500 a year is to be invested and the proceeds applied to charitable purposes on certain stated conditions.

The death is announced of Fleet Surgeon William Brown at the age of fifty-five. He entered the Navy March, 1871, was staff surgeon of the *Monarch* at the bombardment of Alexandria, July, 1882, and during the Egyptian war. He was awarded the medal for the campaign with clasps for Alexandria as well as the Khedive's bronze star. He became fleet surgeon in 1890 and retired the following year.

Surgeon-General C. R. Francis, whose death I mentioned in my last letter, had reached the age of eighty-one. He took his degree at the London University in 1843 and entered the Indian Medical Service the next year and served until 1875. He was at one time professor and principal of the Calcutta Medical College and physician to the hospital. He made important investigations on plague and on snake poisons. He was at one

time editor of the *Indian Medical Gazette*. He was the author of the "Indian Medical Officer's *Vade Mecum*," and several works on Indian medical subjects. Of late years he gave much attention to the temperance question, on which he published two or three essays.

Dr. James Wm. Miller, J.P., of Dundee, died on the 7th instant. He was consulting physician to the Royal Victoria Hospital and director of the Home for Consumptives. He held a high position in the county. He settled in Dundee in 1858 and was connected with the hospital for some forty years. He was also prison surgeon from 1870 to 1898. He was appointed examiner in medicine for the University of Aberdeen in 1880, a post he held for three years.

Dr. J. H. Gornall, J.P., of Warrington, was consulting surgeon to the Infirmary, his first connection with it being as house surgeon, to which post he was appointed in 1865. He had various appointments until 1880, when he became medical officer of health and gave up private practice to devote himself to the duties of that office.

THE EXPERIMENTS WITH CALDAS' YELLOW FEVER VACCINE.

To The Editor of The Medical Record:

Sir: In the interest of truth and medicine, and in order that your readers may form a correct idea of all the facts relating to the experiment made in this city with Dr Caldas' yellow fever prophylactic vaccine, I ask that you will be kind enough to publish this authorized account of it:

Late in July, Dr. Caldas, of Rio Grande do Sul, Brazil, and his assistant, Dr. Bellinzaghi, together with a business agent, arrived in Havana. A day or two afterward these gentlemen called upon me and Dr. Caldas explained the object of his visit to this city. He stated, in substance, that he had discovered the pathogenic microbe of yellow fever and, from cultures thereof, prepared a curative serum as well as a prophylactic vaccine; that both had been thoroughly tested; that he was convinced of their efficacy, and desired the opportunity of demonstrating this efficacy before an official commission. As he had forgotten letters or recommendations to properly accredit him to the government, he cabled to the United States, and, in due time, letters were received by the Acting Military Governor, one from the Secretary of War commending Dr. Caldas to the consideration of the Governor, and one from the Brazilian Consul General, New York, saying in part: "Dr. Caldas is the inventor of the Anti-Yellow Fever Serum, and desires to make experiments in Havana, which, with the kind protection, which I respectfully beg of your Excellency to extend to him, will no doubt greatly benefit both of our countries."

Thereupon, a medical commission was appointed by the Acting Military Governor, to examine into the propositions and claims of Drs. Caldas and Bellinzaghi and submit, in connection therewith, such recommendations as it might deem best for the interest of science and medicine. This commission consisted of the Chief Surgeon of the Department, of Major Gorgas, U. S. A., Dr. Guiteras, Dr. Finlay, and Dr. Albertini, all yellow fever experts. It met at Las Animas Hospital on August 9th, Drs. Caldas and Bellinzaghi being also present. Upon the invitation of the commission, Dr. Caldas described the process by which he immunizes the horse and obtains his curative serum, and that by which he prepares his prophylactic vaccine, an attenuated culture of his microbe. He also explained his procedure to produce immunization in man; as his vaccine, said he, is liable to develop marked febrile movement and other unpleasant yellow fever symptoms, he previously injects a dose of his serum so as to ward off all disagreeable manifestations. The commission then requested that he would demonstrate his pathogenic microbe and describe the method of its isolation and culture; this he formally declined to do, because of his pledge to the company organized to exploit his discovery, and also because he thought such demonstration would, at this time, result in nothing but useless scientific wrangles. This much, however, he was willing to divulge, namely, that his microbe is not found in the blood, but always in the intestines, having been present in every case examined. If he was permitted, he said, to vaccinate non-immune persons, and these are subjected to the bite of infected mosquitos and do not develop yellow fever, the causative relation of his microbe to the disease would be indirectly proved.

Having been asked by what tests he had convinced himself of the efficacy of his vaccine, he stated that, during the past two years, he had inoculated with it twenty-three young men, mostly students, at Rio Grande do Sul, where yellow fever is unknown, previous to their going to Rio de Janeiro, where yellow fever is endemic, and that none of these young men had, so far as he knew, contracted the fever. Upon the request of the commission, he submitted that statement in writing, but without any other evidence or proof than his own declaration. Referring to his curative serum, he informed the commission that in Brazil, as well as in Mexico, he and Dr. Bellinzaghi had obtained with it an average of eighty-five per cent. of cures, a result which, even if correctly reported, did not appear to the commission sufficiently promising to justify further experimentation.

After careful discussion of the subject, the commission decided that, since Dr. Caldas did not intend to demonstrate his microbe and thus put his claim upon a true scientific basis, it should decline all active co-operation in his tests; it, however, recommended that the necessary facilities be afforded him, and stood ready, in its official capacity, to watch results and report upon them.

Thereupon, Dr. Bellinzaghi engaged four non-immune immigrants and, as required by the commission, made with them a written contract whereby they voluntarily offered themselves to be inoculated with Dr. Caldas' vaccine and then to be bitten by infected mosquitos, for a certain stipulated sum of money, to be paid on the termination of the experiment. These four men were sent to Las Animas Hospital and kept in a mosquito-proof, wire-screened room. Upon examination by the commission, two were strongly suspected of being immune and rejected. The other two, young, robust, recently-landed Spaniards, with no one dependent upon them, were inoculated by Dr. Caldas himself on August 15th, three c.c. of vaccine being injected in the gluteal region, they having received, the previous day, an injection of twelve c.c. of curative serum to prevent any excessive action of the vaccine, as already mentioned. No marked effect was noticed as the result of this inoculation. Dr. Caldas had stated that four days would be required to produce immunization; the commission thought best to wait a week. Accordingly, on August 22d, at four P.M., one of the subjects, Paulino Alonso, was brought to the mosquito room, and there, in the presence of the commission and of Drs. Caldas and Bellinzaghi, the nature of the test and the risk he was running having again clearly been explained to him, he signified his desire that the experiment should proceed.

Two mosquitos were applied to his arm, by means of a test tube, and both sucked blood. The history of these two mosquitos is as follows: They had been hatched in a glass jar, and therefore were free from any suspicion of contamination until July 20th, when they were applied to the arm of a yellow-fever patient, on the third day of his disease, and thus infected. One of them, on August 13th, was permitted to bite a young American, who, within three days, developed a mild case of yellow fever; the other was one of two infected mosquitos which, on August 14th, at her own desire, bit an American female nurse, who, four days afterward, developed a very grave case of yellow fever from which she died. It is noticed that a period of thirty-three days had elapsed since the infection of the two mosquitos applied to Alonso.

Dr. Caldas requested that the other vaccinated subject be also bitten by these mosquitos, but the commission refused, thinking it best to await results in this first case before proceeding any further. Evidently, the idea that septic fever could thus be imparted had not yet occurred to Dr. Caldas. Both men were then transferred to Hospital No. 1, away from the painful associations of Las Animas Hospital, where two patients had lately died of yellow fever. There they were placed in a large wire cage, mosquito-proof, but thoroughly ventilated.

The health of the bitten man (Alonso) remained excellent until the 25th; his temperature, taken every three or four hours, showed nothing but the usual normal diurnal variations (from 97° to 99°). Toward the evening of the 25th the temperature rose rather suddenly to nearly 103°, with frontal headache and some backache; the second day the temperature remained about the same, with abdominal tenderness, bilious vomiting, and a trace of albumin; the third day the temperature reached 104°; the vomiting and stools contained specks of blood, the albumin rapidly increased, and an icteric hue became perceptible. The want of correlation between temperature and pulse was also evident. On the fourth day the usual defervescence occurred. In other words, the man had a typical case of yellow fever, a very serious one, but is now fortunately out of danger. That the case was plainly one of yellow fever was recognized not only by all the members of the commission, but by every one of the several Havanese experts invited to examine it. It is hardly necessary to say that Dr. Caldas was given the entire freedom of the ward; but after his patient fell

sick, his visits were few and short, and his examinations perfunctory; on the morning when the commission met for the purpose of formulating its official diagnosis, he declined to be present.

Drs. Caldas and Bellinzaghi would not admit that the disease was yellow fever, and to the last have stoutly denied the possibility of such a thing. For them, it was nothing but a case of septic infection. The commission having asked Dr. Caldas to put in writing the reasons upon which he bases his diagnosis, he readily complied. After describing the symptoms of yellow fever, as he understands them, he proceeds thus: "None of these symptoms were presented by the patient, except the thermic rise (not ushered in by chills) and the strange drops of temperature of the two preceding days, drops that only occur in putrid infections such as those produced by dissecting cuts. No physician experienced in yellow fever can diagnosticate this disease yellow fever in the absence of all the above-described symptoms; on the contrary, any experienced practitioner will affirm that we have here nothing but a septic infection. Any kind of a hemorrhage which may appear, as well as the presence of albumin in the urine, does not invalidate my diagnosis, for it is known that the ptomaines of putrid substances produce these symptoms through a paralysis of the vasomotor nerves. That mosquitos may transmit yellow fever, nobody denies; not because they have sucked the blood of yellow-fever patients, from which they can only obtain septic matters, but because they have lived in an environment contaminated by the dejections and vomit of yellow-fever patients."

This declaration puts Dr. Caldas in a strange and unenviable attitude. He believes that mosquitos which have bitten yellow-fever patients can transmit only septic infection, and yet he proposed that those mosquitos should be used to test the value of his vaccine! True, he believes that mosquitos can convey yellow fever when they have lived in a contaminated environment, but he knew that our mosquitos, hatched from the eggs in glass jars, had been kept away from possible infection, and therefore, according to his pretended belief, were useless for his purpose. His acceptance of our mosquito test leaves no reason to doubt that, had the result been negative, he would have claimed a triumph for his prophylactic vaccine.

Now, Mr. Editor, the transmission of yellow fever by mosquitos is no longer a probability or a good working hypothesis, but a demonstrated fact and an established doctrine. The experiments carried on in Havana by Major Reed and others are as convincing as any mathematical proof. Twenty experimental cases of yellow fever, the direct result of the sting of infected mosquitos, should leave no room for doubt in the most skeptical mind. According to Dr. Caldas, these twenty cases were all of septicemia, and none of the yellow fever experts of Havana had even suspected it!

That the pathogenic organism exists in the blood is made clear not only from the agency of the mosquito in transmitting the disease, but from the four cases of transmission by direct blood injection successfully effected by Major Reed. Therefore, what are we to think of a serum and vaccine prepared from an intestinal microbe?

The commission having come to the conclusion that the vaccine prepared by Dr. Caldas is useless as a prophylactic against yellow fever recommended that all further experiments with it be discontinued.

V. Havard, M.D.,
Major and Surgeon, U. S. A., Chief Surgeon.

Havana, Cuba, September 2, 1901.

LETTER FROM PERU.

(From our Special Correspondent.)

VEXATIONS OF QUARANTINE—TYPHOID FEVER—VERRUGA.

Arequipa, Peru, July 15, 1901.

There was a report that yellow fever existed in Guayaquil, so a steamer coming from San Francisco and Panama which touched at Guayaquil and subsequently had a death of a passenger, on reaching Peru was ordered into quarantine. I understand that if proper evidence had been taken it would have been discovered that the passenger did not die from yellow fever. The steamer, to avoid quarantine, did not enter any more Peruvian ports, but went direct to Chile with its passengers and mails for Peruvian ports. In Chile she was admitted as clean—sufficient time having passed to show there was no yellow fever on board, and perhaps Chilian officials took a little more trouble to ascertain the cause of the passenger's death.

For the last six months there has been a slowly progressing epidemic of typhus fever. It began in a village about five miles distant from the town. Thence it spread to other villages and at last reached the town. The epidemic is not very general, as contagion, probably owing to dryness, sunlight, and fair ventilation, is not very marked. How it began in the village I have been unable to ascertain, the condition of the village and villagers being very different from those that existed in Edinburgh forty years ago, when I saw epidemic typhus. A medical student, Barton, of the University of St. Mark, Lima, is said to have discovered the micro-organism of the disease called Peruvian "verruga." I heard that he was preparing a pamphlet on the subject, and wished to give you some extracts, but as yet it is not published. A plant, "Budleia Incana," native name "Oushuar," has been recommended as a remedy in this disease, being so used by the natives of certain districts affected. It is to be tried in a hospital in Lima. In the south of Peru "verruga" does not exist. I have seen only a few cases which came from the North.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 5, 1901.

The Chemical Properties of Leucocytes.—Edward T. Williams adopts Ewing's classification of leucocytes (substituting English for Greek names) into acid, neutral and alkaline. The nuclei of all these classes are acid, since they stain best with alkaline dyes. The bodies of the normal uninuclear leucocytes are also acid; those of the normal multinuclear cells and of the neutral myelocytes (the latter found only in disease) are neutral; those of the eosinophile leucocytes and myelocytes are alkaline, since they take only acid stains. The alkaline leucocytes are found in large numbers only in disease. The author assumes that the acidity of the bodies of the uninuclear is due to the presence in them of nuclein. This disappears, possibly as the result of decomposition, from the bodies of the multinuclear (neutral) cells. The author inclines to the old doctrine, rejected by Ewing, that young uninuclear leucocytes ultimately develop into multinuclear by division of the nucleus. The alkaline leucocytes, which are almost universally the products of disease, are regarded by Williams as dying forms, their protoplasm being in the process of breaking up and of resolution into nitrogenous alkaloids (xanthine, spermine, etc.)

The Indications for Operation in Malignant Neoplasms of the Stomach.—Charles Green Cumston holds that the surgical treatment of carcinoma of the stomach is indicated not only when stenosis is present, but also as a radical cure of the cancer itself. If under the actual conditions, which are bad, resection has radically cured only a few patients, it has at least given, in more than thirty-three per cent of the patients operated upon, a new lease of life, without suffering, of from one to eight years. Under the same conditions the operative mortality has been reduced to twenty, fifteen, and even ten per cent. In every case in which carcinoma of the stomach is suspected, an immediate exploratory laparotomy should be advised, he says, and every neoplasm that can be removed from the stomach should be excised, no matter what its nature may be. The surgeon should not wait for a clinically confirmed diagnosis of cancer of the stomach, because an exploratory laparotomy is justified in every case where the patient is afflicted with gastric troubles, when (1) analysis of the gastric juice shows an absence of pepsin, and the presence of lactic acid, and (2) when medical treatment carefully conducted is incapable of increasing the body weight and retaining it there.

Under what Circumstances (Excepting Emergencies) is it Desirable to Operate upon Gallstones for Radical Cure or for Relief.—Maurice H. Richardson discusses this question at some length, weighing the arguments for and against early operation, himself taking the view that gallstones should be removed at the earliest favorable moment after the diagnosis has been made, unless there are contraindications in other viscera or in the patient's general condition. Inasmuch as the diagnosis of gallstones can be made only when they begin to offend (excepting, of course, during abdominal operations for other causes), gallstones should be removed either as soon as they begin to offend or at the most favorable period after their immediate ill effects have had time to subside. By the earliest favorable moment he means that period of time when there is no infection of the gall-bladder to contaminate the field, no impaction in the common duct to increase the difficulties and dangers of dissection, and no jaundice to induce hemorrhage or to impair the patient's power of recovery. In many cases the favorable moment follows recovery from the disturbances of a transitory biliary colic unattended by jaundice; in others it follows the disappearance of jaundice after passage of the stone; in others, the subsidence of fever and other signs of a biliary affection. In

all cases of jaundice one should wait a reasonable time for that favorable moment, in the hope that the stone may escape from the common duct into the duodenum and that bile may reappear in the stools.

New York Medical Journal, September 7, 1901.

An Unusual Case of Gastric Ulcer.—F. H. Murdoch reports a case of this kind occurring in a hotel keeper, aged thirty-three years, whose trouble began with distress after eating, bloating and belching. From time to time he had attacks of severe gastric pain, obliging him to lie down. Temporary relief followed the vomiting of a large amount of hot, sour fluid. Examination of the stomach contents after a test breakfast, revealed absence of free HCl, but rennet and pepsin were present. Lactic acid was absent. Later examination showed the presence of HCl in the vomitus. On one or two occasions he vomited blood. The peculiar feature of the case was the large amounts of hot, sour fluid vomited. This proved to be gastric juice mixed with particles of food. Stomach washing afforded great relief. Intense thirst was a feature of the case.

This periodic continuous flow of gastric juice was first described by Reichman, and is known as Reichman's disease, or gastrosuccorrhœa continua periodica, to distinguish it from the chronic form of the disease.

Imperative Conceptions.—H. T. Patrick says that by imperative conceptions he means ideas, mental impressions or emotions, nearly always painful or disagreeable, morbid in their intensity and in the persistence with which they recur in spite of the wish, will, and unimpaired judgment of the patient. The term "imperative ideas" is synonymous. With few exceptions, cases may be divided into two categories, phobias, or fears, and the doubting or questioning psychosis. In many instances both fears and doubts are present. These symptoms are peculiar, often puzzling, and apt to be confounded with hysteria, hypochondria, neurasthenia, and insanity. It is not fair to rank imperative conceptions as manifestations of neurasthenia or hysteria. At least, if this is done the bounds of these two diseases must be considerably extended—extended, indeed, to such an extent as to overlap each other by a very considerable margin. The same individual may have neurasthenia or hysteria and imperative conceptions. While in certain persons the strain and worry of imperative conceptions may bring about a neurasthenic state or induce hysterical outbreaks, relatively few of these patients have hysteria, and many of them have no neurasthenia. Some of the phobias bear a striking resemblance to hypochondria—at least, to paroxysmal hypochondria, if there could be such a thing—but in hypochondria the patient is continually convinced of the existence of some malady. He may be apparently convinced to the contrary by the arguments of his physician, but this conviction is never deep and always evanescent. On the other hand, the phobic patient, even in the throes of a paroxysm, has no real conviction of danger or disease.

The Therapeutics of Whooping Cough.—T. J. Mays advocates the application of counter irritants over the region of the pneumogastric nerves in the neck and states that, in his experience, this method is the only one which leads to any notable amelioration of symptoms. His method is thus described:

Trace the pulsating carotid artery from behind the angle of the lower jaw to the clavicle on both sides of the neck. This will be a landmark for finding the pneumogastric nerves, which lie in close proximity and slightly behind the carotids. Gentle massage and kneading of this region of the neck, every hour or two, yield beneficial effects in many cases of this disease. The application of a strip of mustard plaster, about two inches wide, from the angle of the lower jaw to the clavicles on each side of the neck two or three times a day, until the effects of the mustard are evident, is almost sure to cause amelioration of the spasmodic cough. Equal parts of gum camphor, chloral hydrate, and menthol, applied over this region, are also very useful. Painting the same area with tincture of iodine, twice a day, until irritation of the skin is produced, is a beneficial procedure. Finally, in very stubborn cases the hypodermic injection of silver nitrate over the vagi must be resorted to in accordance with the following plan: Lift the skin over the vagus between the thumb and the forefinger of the left hand, introduce the hypodermic needle just under the elevated skin, and inject five minims of a two-and-a-half per-cent. solution of cocaine hydrochloride. Detach the syringe from the needle and allow the latter to remain in the puncture. Wash out the syringe with water, draw a two-and-a-half per-cent. solution of silver nitrate into the syringe, attach the latter to the needle, and throw in from three to six minims of the silver solution.

Journal of the American Medical Association, Sept. 7, 1901

Traumatic Affection of the Uvula.—S. Oppenheimer reports a case in which the end of the stem of a corn-cob pipe was violently forced into the throat of a man of thirty years. Pain was severe and there was considerable bleeding. There was a deep laceration on the left side of the tongue and the uvula had been partially perforated by being jammed back against the posterior pharyngeal wall, the posterior mucosa of the organ, however, was not pierced. Ichthyol was applied and an astringent mouth wash ordered. Relief followed in a few hours.

Albuminuria in Disease of the Kidney in Infancy and Childhood.—J. R. Rathmell says that renal disease in children generally consists of active hyperemia and inflammation following the contagious diseases, especially scarlet fever. Under the age of fifteen years there is less likelihood of disorders of the circulation than in later life. Cachectic conditions often lead to amyloid changes and this in turn to chronic albuminuria in children as well as in adults. Physiological albuminuria may occur at any period of infancy or childhood, but is most common between the ages of five and fifteen. Occurring alone without the presence of blood cells or other abnormal elements, it indicates absence of pathological change. The author gives a full list of the causes of albuminuria and then, the clinical history of a case occurring in a boy of four years in which the cause was probably a chronic parenchymatous nephritis immediately followed by an acute nephritis, a condition rarely found in children. This case resulted fatally. Another case with similar symptoms recovered. In such cases the prominent symptoms are albuminuria, high specific gravity, and œdema. These symptoms are especially found in interstitial and chronic parenchymatous nephritis, active hyperæmia, catarrhal nephritis, parenchymatous degeneration, passive hyperæmia, and acute nephritis. In acute nephritis the amount of albumin depends upon the extent of involvement of the glomeruli, and the amount of casts depends upon the extent of the tubules affected.

Diabetes Mellitus in Childhood.—A. C. Cotton gives a general review of etiology, symptoms and treatment of the disease. Dietetic treatment offers the only palliation and the author believes that more ought to be done than is done along the line of prophylaxis. He states that it is now believed that diabetes, if not an hereditary disease, at least develops along the lines of a somewhat positive diathesis. To the extent that the function of the family physician is supervisory over his patients, may he hope to avert such disorders by controlling their development through attention to hygiene, in order that the young, whose immediate or remote ancestry show diabetes, gout, tuberculosis, neuroses, or even syphilis, should be sedulously guarded. Dietary errors, such as ingestion of food beyond the child's capacity for absorption and assimilation, preponderance of saccharin substances, as sweetmeats, confections and pastries, must be carefully avoided.

Especial attention should be paid to the functions of elimination and to the entire gastroenteric tract. Especially should we protect these children from mental strain, shocks, frights, trauma, and exposure to inclement weather, since cases are reported in which the development of glycosuria was preceded by such disturbance. In a child thus carefully observed, diabetes may be anticipated by the appearance of pregly cosuric signs, such as incontinence of urine, muscular debility, irritability, with progressive emaciation in spite of voracious appetite, even though a single test of the urine fail to reveal sugar. The importance of an early diagnosis is evident, for it is admitted that success in treatment bears an inverse ratio to the previous continuance of the disease.

The Immediate and Remote Effects of Brain Injury.—D. S. Fairchild offers the following conclusions: 1. Violence of no great intensity when applied to a limited area of skull may cause a fracture with only momentary displacement with a rupture of a meningeal artery, or a rupture of an artery without fracture. 2. A localizing injury, which may lead to a fracture without displacement and hemorrhage does not, as a rule, cause a serious permanent brain lesion if early and judicious surgical treatment is employed. 3. A fracture may occur without apparent displacement, yet a real localized pressure on the brain exist which may cause irritative changes involving a more or less extended sclerosis and remote secondary results, as epilepsy or mental impairment. 4. A blow may be received on the head which may produce a more or less extensive laceration of the scalp which in itself is not serious. But the fall from a height or from a rapidly moving train may produce more or less extensive contusion or

laceration of brain tissue leading to serious immediate or remote effects. 5. A fall from a height or moving train may without a fracture cause, directly or indirectly, a contusion or laceration of brain tissue, or so disturb the cerebrospinal fluid as to primarily bring about such changes, and cause immediate results or secondary serious remote effects by inducing degeneration and final interstitial changes producing insanity. 6. An injury may be of such a character as to produce a localized wound of the brain that may heal with the production of scar tissue which may extend, may or may not undergo cystoid or other degeneration with serious remote effects. 7. In the absence of localizing or other definite symptoms to indicate the nature of the lesion, the character of the accident and the manner in which the force is applied is of great value in reaching a conclusion as to the probable nature of injury to the brain.

American Medicine, September 7, 1901.

Methylene Blue in Tuberculosis.—Cornelius R. Lane reports that he has had two cases of tuberculosis pulmonalis in the second stage, to whom he administered one grain of methylene blue three times a day, and the patients improved very rapidly. This substance is eliminated in the bronchial mucus, and the cellular elements, while some of the bacteria in the sputum are stained blue.

The Manifestations of Rheumatism in Children.—William Fitch Cheney, in discussing this subject, speaks first of manifestations in joints. These are far less severe than those that occur in adults. The swelling is less, as is also the pain, while the redness is often entirely absent. As to the heart, the endocardium is very readily involved in children, being nearly twice as common as in adults. The writer is led to believe from his own personal observations that the place of chorea among rheumatic manifestations is rather a doubtful one. Some believe that chorea is in itself a rheumatic manifestation, no matter whether others occur or not. He has observed two cases of rheumatic purpura and one case of subcutaneous nodules. He thinks it very doubtful whether tonsillitis should be spoken of as a rheumatic manifestation at all. Finally, every pain in the limbs of a child should receive careful attention, and should never be considered trifling. Endocarditis is always to be feared in the rheumatism of children, and it is far better to keep a child at rest, if the case is not rheumatism, than not to keep it at rest if it is.

Medical News, September 7, 1901.

Generalized Vaccinia.—John H. Huddleston states that the cause of this affection is disputed. Some authors believe every case to be an autoinoculation. When the skin is eczematous, autoinoculation may produce an almost unlimited number of pustules over the affected area, and such cases are often reported as generalized vaccinia. The presence of eczema or other skin disease does not in itself constitute a marked predisposition to generalized vaccinia. The diagnosis, although usually easy, may be very difficult. Differential diagnosis must be made in some cases from varicella, pustulous syphilides, miliaria, the pustular eruption of bromides, impetigo contagiosa, and the vesicular eruption which sometimes follows vaccinia. This vesicular eruption, exactly like a roseola or an urticaria, sometimes follows vaccination, just as all three sometimes follow antitoxin or drug administration. Eruptions of the roseola type may come on in the first three days, vaccinia usually not. The resemblance may be extremely close and the final test in any case is inoculation.

A Study of the Temperature Laws in Epilepsy, Based on One Thousand Observations.—William P. Spratling gives the following conclusions. After making due allowance for diurnal variation, the general grand average of cases of all types showing increased temperature after seizures is fifty-five per cent. In many petit mal and psychic attacks, in which muscular activity plays so small a part, and in which the temperature is often increased after seizures, such increase is undoubtedly due to a disturbance either of the heat center that is thought to exist in the cortex of the brain, or of the center or centers that observers believe have been located in the corpus striatum and optic thalmus. Subnormal temperatures follow epileptic seizures in greater proportion after grand mal than after petit mal, or psychic seizures, the proportion being fifteen per cent. to ten per cent. Although certain of these cases have abnormally low temperatures in health, there will usually be found in these cases some chronic disease or general asthenic condition of long standing that lowers the vitality. The temperature in serial attacks runs uniformly higher than in isolated attacks, but not so high as in status epilepticus.

Autotoxæmia.—William W. Pennell declares that this condition is dependent upon the absorption of harmful substances from the intestinal or genito-urinary tracts into the blood; these poisons are the result of either defective metabolism and elimination or fermentative and putrefactive processes, or both, and they produce well-defined symptoms. There is a possibility of convulsions and death from autotoxæmia. If a patient is constipated, sallow-faced and pessimistic, with an offensive breath, it will probably be found that he drinks very little water. He has headache and backache, takes cold easily, dreads impotence, has palpitation of the heart and gastric distress. He is bilious, subject to attacks of vertigo, has a muddy skin, and fetid breath. In the female, there is, besides these symptoms, leucorrhœa, and often irregular and suppressed menstruation. If there be a tendency to phthisis, the toxæmic condition increases the asthmatic attacks. These patients are also liable to skin diseases. Troublesome erythæmia often results from intestinal infection. Spirit-drinking both produces intoxication and is the cause of the many autotoxæmias. Lithæmia, or modified gout belongs to this list of maladies. Biliousness and hepatic torpor are for the most part now looked upon as autotoxæmias. As to treatment, creosote has an antibacterial effect in the bowels. Water, calomel, resorcin, salol, tetanaphtol, sulphate of magnesia and colonic flushing are agents at our command to cleanse the body of harmful materials and to give renewed vigor.

Philadelphia Medical Journal, September 7, 1901.

The Treatment of Carcinomatous Growths by Roentgen Rays.—George G. Hopkins, in his work with the *x*-ray, uses the soft tubes entirely. The theory of their use in the treatment of carcinoma is, that their power of altering tissue is in proportion to the power of that tissue to resist any destroying agent. The embryonic cells which largely compose carcinomatous tissue, are made up of unstable molecules, and can readily be rearranged or even destroyed. In the former case, they assume a normal action once more. For a protection to those parts which are not to be treated, the writer uses several layers of lead foil glued to pasteboard or more flexible material. He varies the distance of the diseased part from the tube from twelve to thirty inches, according to the desired effect. The first change noted in the tumor is the decrease in its density. The results of this treatment have been most happy so far.

On Streptothrical Infections.—John H. Musser states that, from a clinical standpoint, but little distinctly new is presented in streptothrical infections. In bacteriology the streptothricæ stand between the moulds (hyphomycetes) and the bacteria, both of which organisms they partly resemble. It is now known that besides the two streptothrical infections, actinomycosis and madura foot, there are various conditions due to other members of this group. There are, undoubtedly, many species of streptothrix having morphological and cultural differences of greater or less degree. The writer concludes from his study of the subject: 1. That the streptothrix in some varieties is pathogenic to man, and gives rise to inflammatory, suppurative, and necrotic lesions in (*a*) the lungs, and (*b*) the skin, and (*c*) by metastasis, probably in the brain and spinal cord and rarely other organs (the kidneys). 2. That, while this pathogenicity is more than likely, and is primary, yet it must be remembered, it may be a secondary growth in the course of other infections.

Post Typhoidal Ulceration, and Abductor Paresis of the Larynx; Tracheotomy; Recovery.—D. J. Gibb Wishart reports the case of a man aged forty-one years, who, in the course of an attack of typhoid fever, suffered from time to time with laryngeal irritation. There was periodic attacks of dyspnœa. The writer gives the following description of the condition found on examination. There was no tenderness, swelling, nor fixidity revealed by palpation of the neck. Tracheal tugging was marked. There was decided anæmia of the mouth and oropharynx. The vocal cords were almost in contact, and the patient seemed unable to abduct them, except very slightly. The cords were congested, and appeared swollen and somewhat nodulated, the swelling being chiefly confined to the inferior surface of the cords, the infracordal portion of the larynx appearing to be bounded on either side by a rigid wall, extending diagonally outwards from the free edge of each cord. The left cord was notched towards its posterior extremity, the notch being filled by a pure white slough, and measuring about 6 mm. in each direction. The edges of the notch were congested, uneven, and undermined. Later, the condition became so much worse that the trachea was opened in the high position. In a little over a month the tracheotomy tube was removed, and the patient made a good recovery.

Berliner klinische Wochenschrift, August 19, 1901.

A Contribution to the Study of Tetany.—A. Westphal reports two cases in which this condition was associated with epilepsy. Both patients were women, one of whom, six years ago, was operated upon for a goiter, the tumor, however, not being entirely removed for fear of causing cachexia strumipriva. In spite of this precaution, typical attacks of tetany developed on the second day after operation, and with the exception of a single period of remission, during a pregnancy, continued until the patient came under observation, in January, 1900. Shortly after the onset of the original trouble the condition was complicated by the development of true epileptic attacks, while the patient's mentality underwent a steadily progressive degeneration, and in addition a gradual failure of vision was noted which was found to be due to double cataract formation. Under treatment with thyreoiodin, in doses of three grains three times daily, great improvement resulted, and from the beginning of July to the time of discharge, six months later, neither tetanic nor epileptic attacks took place, while the mental condition returned nearly to the normal. The other patient was an epileptic dement, also presenting the typical picture of tetany, Trousseau's, Chvostek's, and Erb's signs all being present. An attempt at treatment with the thyreoiodin had to be abandoned on account of the development of toxic symptoms.

Experimental Contributions to the Question of Tuberculous Toxins and Antitoxins.—L. Frenkel and O. Bronstein endeavored to reproduce the various forms of toxin described by Maragliano, and to determine to how great an extent the serum he has elaborated is specific, and whether it is able to neutralize the effects of the toxins on the animal body. Maragliano's aim was by the use of his toxins to immunize horses, and thus produce specific antitoxins, his idea of therapy being to neutralize the toxin which is constantly being produced in the tubercular foci under the supposition that the body will then be able to take care of the infection. The conclusions reached by the authors as the result of work extending over ten months, and during which 150 guinea pigs were used, are as follows: By simple technical processes it is possible to obtain a whole series of products from cultures of tubercle bacilli. The most important of these are the fluid and precipitated toxin, the watery tuberculin and its precipitate, the fat-free bacilli (bacilli digrassati). Most of these bodies have well-marked toxic properties which may be accurately estimated, and when injected in sufficient amounts kill the animals under the production of typical manifestations. It is possible, by the administration of graduated doses slowly increased to the maximum, to produce in the animals an active immunity, and the serum of such animals possesses a marked antitoxic power which can experimentally be demonstrated for each separate toxin.

Münchener medicinische Wochenschrift, August 20, 1901.

Typical Albumosuria in Genuine Osteomalacia.—G. Jochmann and O. Schumm describe a case in which complete microscopical and chemical examinations were made and it could be definitely shown that the Bence Jones body can occur in true osteomalacia. The patient was a woman of thirty-seven, who, after an illness of about six months, died of what on autopsy was found to be osteomalacia of the spinal column, sternum, ribs, pelvis, and long bones. The urine gave reactions showing the presence of the Bence Jones body, and from the blood obtained post mortem a substance which proved to be a deuteroalbumose was obtained. The authors call attention to their case as disproving the relationship which Kahler and Rosin assert exists between albumosuria and multiple myeloma, and state that the presence of this symptom does not assist in the differentiation of sarcomatosis of the skeleton of the trunk and true osteomalacia.

A Type of Tracheal Hæmoptosis.—G. Avellis for a long time was unable to discover the origin of a daily matutinal hæmoptysis of moderate severity, and accompanied by cough, from which an otherwise healthy middle-aged man was suffering. All the usual sources for such bleeding, mouth, nose, pharynx, and larynx, gave no clue, and the examination of the lungs was also negative. Finally, on examining the larynx immediately after an attack of the trouble, a few drops of blood were seen oozing from the anterior portion of the upper tracheal rings, and cauterization of this spot with chromic acid remedied the trouble. The author explains the formation of this place of weakened resistance on the ground that the very marked chronic constipation from which the patient suffered caused him to do a great deal of abdominal straining. This means a preliminary closure of the glottis, with a subsequent relaxation and rapid escape of the air formerly compressed in the lungs, and therefore an often repeated aspiration of the tracheal mucous membrane, this being the region over which the air travels fastest. A relaxation of the tracheal mucosa follows, which permits the formation of varicosities which may be the site of bleeding.

Two Cases of Suture of the Diaphragm, with Trans-Diaphragmatic Suture of the Liver and Kidney.—C. Schlatter, who has already reported a similar case, adds two more to the small number of perforating wounds of the diaphragm described in the literature. Both patients were young men who received their injuries at the hands of a band of Italian street thieves. On coming under observation shortly afterwards one of them was very anæmic, and there were signs of right-sided pneumothorax with rapid respiration. Between the eighth and ninth ribs in the axillary region there was a perforating wound about one and one-half inches long. On resecting the ninth rib and enlarging the pleural wound an opening through the diaphragm was discovered with two wounds of the liver and a deep wound of the right kidney. These were disinfected and closed by five sutures in the kidney, four in one liver and one in the other, and the diaphragm was similarly repaired by a row of interrupted silk sutures. The skin wound was closed without drainage and the patient discharged entirely well one month later. The other patient's injury was much less serious in that there was no damage to the abdominal viscera, and he, too, made an uninterrupted recovery after suture of the diaphragmatic incision. The question of whether or not to resect a rib and inspect the diaphragm after perforating wounds of the pleura is often a difficult one to settle and the operator must take into consideration the force and direction of the injury, together with the nature of the instrument with which it was inflicted. In one of the above cases the severe anæmia and vomiting gave the clue.

French Journals.

Paramyoclonus Multiplex.—G. Carrière believes that the affection described in 1881 by Friedreich under the name of *paramyoclonus multiplex*, is due to a functional hyperexcitability of the motor neurosis, the hyperexcitability being exceptionally due to an anatomical lesion, in relation sometimes with neurasthenia, but more often with hysteria. Practically, he thinks that treatment of this affection should always begin by an attempt at hypnotic suggestion.—*La Presse Médicale*, August 7, 1901.

Influence of Lecithine on Nutrition.—According to G. Carrière the administration of lecithine to normal children has produced a striking increase in weight. However, this effect decreases in proportion as the organism becomes accustomed to it. As to its influence on the urine, the quantity is not modified. The reaction remains acid, although the acidity is slightly diminished. The rate of urea increased greatly during the first weeks, after which the increase becomes less noticeable. Phosphoric acid is diminished during the first three weeks, then rises to normal. The sulphates are not modified.—*Le Bulletin Médical*, August 17, 1901.

Concerning Microbes in the Brain, the Cerebrospinal Fluid, and the Blood, in Two Hundred Cases of Mental or Nervous Troubles.—Maurice Faure and Laignel Lavastine from their researches in this subject, state that they have never discovered in the brain, cerebrospinal fluid or blood of patients affected by the nervous infections, a microbe to which they could impute a rôle in the genesis of the disease. This result of their work differs from the reports of many others who have worked in the same lines. They believe these mental troubles occurring in the course of infections to be toxic in origin. —*Le Bulletin Médical*, August 14, 1901.

Koch's Bacillus in the Stools of Tuberculous Patients.—Anglade declares that the rectal passage plays a most important part in the elimination of Koch's bacillus. Pulmonary tuberculosis is often, if not always, accompanied by intestinal tuberculosis. The latter may be primitive, and indeed, may exist by itself. In tuberculosis ulcerations of the intestine, Koch's bacillus possesses an extraordinary activity. And even among patients whose intestines seemed healthy, examination of the stools has given positive results. The writer says that he will speak more at length from the prophylactic standpoint, after he has completed his work on the subject.—*Gazette Hebdomadaire de Médicine et de Chirurgie*, August 1, 1901.

Sudden Death in the Course of Diphtheritic Intoxication.—Ch. Aubertin and L. Babonneix report the case of a young man of twenty-five years, who died suddenly a month after he was stricken with diphtheria. Autopsy disclosed a diffuse leucocytosis in the myocardium. The most striking interstitial lesion was the diapedesis. The parenchymatous lesions were far less intense. The his-

tological examination in fact showed the acute interstitial lesions to be predominant, the parenchymatous lesions to be slight. The bacilli which were found resembled those of putrefaction. There was an absence of Loeffler's bacillus, of the streptococcus and of the staphylococcus. The authors believe, from the study of this case, that diphtheritic myocarditis with predominating interstitial lesions is sufficient of itself, independent of any nervous lesion to determine sudden death. —*Gazette des Hôpitaux*, August 8, 1901.

Foreign Work on Methylene Blue. J. Castaigne and X. Bender give a resumé of experimental work on methylene blue, and among the results obtained by various authorities, they describe those of Pédenko, who has observed seventy-nine cases. Of these, seventeen were acute nephritis, two of which were verified anatomically, ten were cases of chronic parenchymatous nephritis; sixteen were cases of interstitial nephritis (nine autopsies). This author concludes that elimination of methylene blue depends to a great extent on the anatomical condition of the kidney, the more deeply and extensively the excretory power of the kidney is affected, the greater are the alterations in elimination. It is important always to use the same preparation of the blue, and to study its course systematically. In nephritis, if the maximum degree of coloration of the urine by the blue is near type I, which is taken as a standard, and if the duration of elimination does not last longer than from fifty-five to sixty-five hours, then no renal alterations exist, or at least, the lesion is very slight. —*Gazette des Hôpitaux*, August 3, 1901.

Annals of Surgery, August, 1901.

An Operation for Saddle Nose.—Fred. Walker Gwyer describes the operation which he employs, which is a plastic flap operation, and consists, as he expresses it, in utilizing the material at hand, and like a landscape gardener by a system of grading and equalization destroying the ugly portions by filling in hollows with matter taken from elevations. The advantages of his operation are: The absence of foreign bodies, correction made with living attached tissue having its own blood supply, ability to correct at the same time minor deformities, the field of operation being in sight, and a minimum of scar.

The Artificial Production of Connective Tissue by means of Injection of Agar-Agar.—Simon Pendleton Kramer obtained excellent results in his experiments on rabbits. The process by which connective tissue replaces the agar jelly is precisely the same as that by which a thrombus becomes organized. A neutral four per cent. solution of agar-agar in physiological salt solution is used, with the addition of formaldehyde in the ratio of 1 to 2,000 to insure an aseptic condition of the jelly, which should be injected at a temperature of 40° C., the syringe having been previously warmed. In the treatment of inguinal hernia, aneurism, hydrocele, bone cavities, tuberculous cavities, etc., it may often be desirable to produce an artificial growth of connective tissue, and the author proposes that experiments be made on the lines here suggested.

Forward Dislocation of the Semi-Lunar Bone.—Percival R. Bolton reports the case of a man of forty-eight years who stumbled and fell heavily upon the thenar and hypothenar eminences of the hand, with the wrist presumably in dorsal flexion. The fluoroscope and radiographs showed the semilunar to be displaced forward, to lie anterior to and against the margin of the articular surface of the radius, and to be inverted, *i. e.* rotated about a transverse axis through 180°. There was also a fracture of the styloid process of the radius. From the diagnostic standpoint the injury simulated in some respects a Colles' fracture, with moderate displacement of fragments, but the radiographs cleared the diagnosis at once. The patient refused incision and passed from observation.

Congenital Anterior Dislocation of the Tibia Treated by Arthrotomy.—John B. Roberts describes a deformity in a child of five years. The tibia was displaced forward on the femur, so that when the child lay on her back the tibia extended upward, making an angle with the plane of the bed of about 50 or 60 degrees. A skiagraph confirmed the diagnosis of anterior displacement of the tibia. Operation was performed by incision, division of the ligament of the patella and lateral ligaments, and reduction of the dislocation. The ligament of the patella could not be reunited, but the four-headed muscle was lengthened by incision, and strong catgut sutures were passed through the tendon of the quadriceps and the lower piece of the ligament of the patella and the tissues in front of the tibia. The result was a straight limb, with restricted motion at the knee joint.

Cancrum Oris Successfully Treated by Excision of the Cautery.—A. Z. C. Cressy, in the case of a child of seven years, cut through the upper lip and cheek very nearly as far as the zygoma, the knife passing through the sloughy mass, which was then dissected away from the cheek and from the gum. Two teeth were removed. The dentoline cautery was then freely applied to all the old tear laid bare. Finally the edges of the incision were drawn together with sutures. The after-treatment consisted chiefly in irrigation of the mouth with boracic acid lotion every two hours, the mouth being also washed out after food. The result is a linear scar across the cheek, somewhat fixed to the upper maxilla, with consequent immobility of the upper part of the cheek. The lower lip moves freely and the upper one fairly well.

The Journal of Tropical Medicine, July 15, 1901.

A Case of Multiple Abscesses of the Liver.—W. E. de Korte reports a fatal case in a man of thirty-five years. The chief points of interest are that symptoms, considered by the patient to be dyspeptic, had lasted four years; that there were attacks of pyrexia during this period, diagnosed as malaria; no sweating or rigors; the very rapid development of the abscess towards the end. Operation was performed, and about four pints of pus escaped. Abscesses were found subsequently to the operation, and further interference was necessary. In spite of this, death occurred twenty-three days after the first operation. The relation of the multiple abscesses to the original one is not known.

Notes on Cases of "Sleeping Sickness" Occurring in the Uganda Protectorate.—J. Howard Cook reports eight cases of this disease, of which two were fatal, one after three and the other after two and a half months. The chief symptom of constant drowsiness seems to be ushered in in different ways, sometimes with giddiness, cough, hiccough, fits (in one case), an unsteady gait, etc. The appetite is increased rather than diminished. One case has already lasted three years. In the blood of five out of seven patients, the *filaria perstans* was found. The facility with which the worms are found in any one case varies from day to day, and there is apparently no relation between the condition of drowsiness and the facility with which the filaria is discovered in the peripheral circulation. As to treatment, arsenic, tonics, and quinine were tried, but had not the slightest effect. Two illustrations of sleeping patients accompany the article.

Archives of Pediatrics, August, 1901.

Nodding and Rotatory Spasm of the Head with Nystagmus in Rachitic Children.—Augustus A. Eshner states that this affection is noted specially during the first year of life, always in children suffering from rickets or other disorder of nutrition or metabolism. The spasm may be rotatory or nodding, or both forms may be present in the same patient. The associated nystagmus may be lateral, vertical, or rotatory, is usually in both eyes, and not always in the same direction as the motion of the head. This condition is to be distinguished from spasmodic torticollis.

The Treatment of the Nasopharynx in Scarlatina.—A. Seibert advocates energetic local treatment in cases of scarlatinous sore throat, and believes that local measures cannot be safely abandoned until an effective serum therapy for scarlatina and its complications is secured. Before the nasopharynx has become obstructed, he uses irrigations of one to five per cent. warm solution of ichthyol; in more advanced stages of scarlatinous nasopharyngitis he uses local applications of fifty per cent. resorcin solution in alcohol. He considers this latter treatment applicable and very easily carried out in the case of young infants.

A Case of Appendicitis in an Infant Seven Weeks Old.—George Blumer and H. L. K. Shaw report the case of an infant in the Albany County Almshouse, who about the fifth week developed an ischiorectal abscess with external and internal openings, followed by general anasarca, and, near the end of the seventh week, by coma. The child died two days after the onset of coma. On autopsy a diagnosis of acute gangrenous appendicitis was made. There were adhesions between the head of the cæcum and the sigmoid flexure, and an abscess cavity between the cæcum and sigmoid flexure, into which the appendix projected; the distal portion of the latter was necrotic. Diagnosis during life was impossible, as there were no symptoms indicative of special abdominal disturbance.

Book Reviews.

THE RETROSPECT OF MEDICINE. Edited by JAMES BRAITHWAITE, M.D., London, and E. F. TREVELYN, M.D., London. Vol. 123. London: Simkin, Marshall, Hamilton, Kent & Co., Limited. 1901.

THIS half-yearly journal not only keeps up its reputation now enjoyed for many years, but in some particulars, shows improvement. The synopsis, arranged alphabetically, gives the most important indications of treatment from the year's output of medical journal articles.

ESSENTIALS OF REFRACTION AND OF DISEASES OF THE EYE. By EDWARD JACKSON, A.M., M.D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic, etc. Third edition; revised and enlarged. Philadelphia: W. B. Saunders & Co., 1901.

THIS third edition contains more page space, and the work, embracing ocular injuries and ocular symptoms of general diseases, and containing 82 illustrations, is more complete and symmetrical than those preceding it. Recent advances have been noted, in so far as they fall within the scope of the work. It is by no means a textbook nor a deep treatise upon the eye, but contains the essentials to enable one fairly well up in medicine to make tests, reach a diagnosis, and apply treatment.

TRAITÉ DE CHIRURGIE CLINIQUE ET OPÉRATOIRE. Par A. LE DENTU et PIERRE DELBET. Tome dixième. Paris: J. B. Baillière et Fils, 1901.

THERE are two parts to this tenth volume of the series, published under direction of the editors named. The first part contains a treatise upon the testicle and diseases of the genital organs of woman. The second part continues the same subject, taking up diseases of the uterine adnexa. The greater portion of the volume, however, is given up to affections of the limbs, dealing chiefly with orthopedic deformities and operations. The present volumes are well illustrated, and published in a manner to conform with those that have already been given out. The articles bear evidence of having been written with much care, and the editors may well be pleased with the results, now that the work has been completed. The choice of authors has, so far as can now be judged, left them nothing to regret.

OUT OF THE PIGEON HOLES. By E. S. GOODHUE, M.D., author of "Verses from the Valley," "Beneath Hawaiian Palms and Stars," "Salt." Alma, Mich.: The George F. Butler Publishing Co., 1900.

THIS is a collection of short essays with an occasional poem written by a medical man in his leisure hours, apparently without special aim and only to think on paper; but later collected together and put into print, chiefly for the author's own satisfaction. That, at least, is our diagnosis, but we may add that they will certainly give pleasure to others that read them, as they have to him that wrote them. They are not all interesting—at least not all equally so, but all of them will bear reading, and many contain food for thought. The reading of essays is like chatting with the author, and we judge from these that Dr. Goodhue is an entertaining conversationalist.

SURGICAL APPLIED ANATOMY. By Sir FREDERICK TREVES, K.C.V.O., C.B., F.R.C.S., etc. New Edition. Revised by the Author with the assistance of ARTHUR KEITH, M.D., F.R.C.S., etc. Illustrated with 80 Engravings. Philadelphia: Lea Brothers & Co., 1901.

THIS little volume is one of a series on various subjects which has proved very popular with students and instructors. The subject of anatomy is gone over rapidly, with special reference to surgical landmarks and relations, and naturally the detail of larger works is omitted, though the anatomy of many surgical conditions is thoroughly described. This edition has brought the book up to the requirements of a modern textbook, and its usefulness will be maintained.

DIE SERUM-, BAKTERIENTOXIN- UND ORGAN-PRÄPARATE; ihre Darstellung, Wirkungsweise und Anwendung. Für Chemiker, Apotheker, Aerzte, Bacteriologen, &c., dargestellt von Dr. Pharm. MAX v. WALDHEIM. Wien, Pest, Leipzig: A. Hartleben, 1901.

THIS work, as its name implies, treats of the preparation, effects, and mode of administration of the various agents employed in orrho- and opo-therapy. It is with astonishment, indeed, that one learns from this book of the number of preparations of this sort—twenty-five antitoxins and twenty-eight organotherapeutic agents, and one wonders how the few kernels of wheat are to be sifted out of this great heap of chaff. The first preparation mentioned is the antitoxin of alcoholic intoxication, the last are the extracts of the ciliary body and of the vitreous humor. Between these, however, we find the unequivocably useful diphtheria antitoxin and thyroid extract, the doubtful tuberculin and ovarian extract, and others of greater or lesser fame. The book is written apparently without prejudice, the author's aim being merely to describe the preparations and their mode of employment, leaving to others the commendation or condemnation of them as therapeutic agents, and it ought to be very useful as a work of reference for all interested in this new therapeutic development. Each of the two parts of the work is preceded by a brief explanation of the theory of action of antitoxin and of organic extracts respectively.

MOSQUITOS: How They Live; How They Carry Disease; How They Are Classified; How They May Be Destroyed. By L. O. HOWARD, Ph.D., Department of Agriculture, Washington, D. C. New York: McClure, Phillips & Co., 1901.

THE mosquito, which was formerly regarded simply as a vixenish vampire and an unmitigated nuisance and disturber of rest, has now been proved to be an active agent in the transmission of at least two, and possibly more, widespread and often fatal diseases of mankind. Its study has therefore become one of very practical importance to the medical man, as well as to the entomologist. Dr. Howard, than whom no one is better qualified to treat of the subject, has done a real service to medicine in writing this book. He describes the different kinds of mosquitos, especially those known to be guilty of spreading human diseases, and shows how they can be distinguished, in their various life cycles, one from the other. The author is an optimist as regards the question of freeing districts and countries from the plague of mosquitos, and believes that the insects may be wholly exterminated by care and perseverance in the execution of proved methods of repression and destruction. Apart from its scientific value, the book is one of absorbing interest to any lover of nature or student of the lives and habits of the lower orders of creation.

ETIDORHPA; or, The End of the Earth. The Strange History of a Mysterious Being and the Account of a Remarkable Journey. By JOHN URI LLOYD, author of "Stringtown on the Pike." Eleventh edition, revised and enlarged. New York: Dodd, Mead & Co., 1901.

A LARGE fraction of mankind has always shown an appetite in its literature for the sort of fairy tale or fable which purports to tell the unrevealed and unknowable secrets of other states of existence; and so it is natural that every now and then some one should be found willing to record his guess at what evolution may do for us some day. Great and sane imaginations have more than once tripped over this rock, as witness the dull, portentous, and unbeautiful "Seraphita" of Balzac. It would seem that the human imagination is capable of dealing only with human experience, and when it soars or sinks beyond that the results are not happy. "Etidorhpa" is no exception to this rule. It is probably intended to be an allegory, but that does not make it any better reading. The story is that of a man who announced his intention to reveal the mysteries of a secret order, and in punishment therefor was kidnapped, dropped into a hole in the ground in Kentucky, and conducted thence, by a creature without clothes and with a forehead extending to the alæ nasi, to and past the center of the earth, to the domain of an entrancing female (whether human or not we are not told), whose name gives the title to the book. This name is that of the goddess of love in mirror-writing, and is borne by a creature who, we are led to believe, is all that the heart of man or angel could desire, more beautiful than a houri, and with a soul, or something akin to it, purer than the driven snow. But that is all we learn of her. As soon as the weary wanderer finds her he soars back to the surface of the earth, to recount his journeyings to an unwilling witness in Cincinnati, who is made to listen to him at the point of the knife. The author of this tale has shown himself admirably fitted to deal with human experience in his most interesting "Stringtown on the Pike," and we hope that he will in future follow this lead rather than that of the uncanny Etidorhpa. He has the talent of the story writer in full measure, and it will be a pity to waste it in the fabrication of weary allegories and unhuman imaginings.

LECTURES ON THE HISTORY OF PHYSIOLOGY DURING THE SIXTEENTH, SEVENTEENTH, AND EIGHTEENTH CENTURIES. By Sir M. FOSTER. New York: The Macmillan Company, 1901.

No more fitting subject could have been chosen by Sir M. Foster for the "Lane Lectures," delivered at the Cooper Medical College in San Francisco, in the autumn of 1900, than the history of physiology. That it is an old-world history need scarcely be stated; that much of the work of those early seekers after truth was done against opposi-

tion from both Church and State is equally true. Moreover, the force of tradition, chiefly Galenic, had to be overcome. The scientific attitude of mind, as we know it to-day, had not developed. The testimony of the senses counted as nought if Galen contradicted; yet in spite of these obstacles, great truths were observed and taught, and finally published. The seeds of the present day scientific harvest were sown. Except for the opposition of the anti-vivisectionists, scientific research along all lines is now encouraged to the fullest extent.

In the limits of a review it will be impossible to refer to many details of this absorbing story. Some of the discoveries were made before the world was ready for their acceptance and died almost in their birth. Under the influence of Stahl, such was the fate of Mayow's discovery of oxygen in 1668. More than a hundred years later, in 1777, Lavoisier rediscovered oxygen and gave it its present name. Richard Lower showed, in 1665, that the heart would beat for awhile severed from all its connections, and that ascites could be produced by ligating the vena cava. Perhaps still more remarkable was the discovery by Brunner (*circa* 1687) that removal of the pancreas from dogs produced polyuria and bulimia, his own statement of one experiment being that "it was especially to be seen that the animal made water very frequently, and that he was very thirsty, drinking largely of water in proportion to the discharge of urine." Foster truly remarks, "What a zigzag path, how unlike a straight line, is man's progress in search of truth. Here is Mayow reaching a point far ahead, and Boyle, a little later, had grasped the same fact . . . . and more than a hundred years afterward Lavoisier reaches the same point as Mayow. . . . If a discovery is made before its time, it withers up barren, without progeny, as did Mayow's."

Compendium der Physiologie des Menschen. Für Studierende und Aerzte, Zweite verbesserte und vermehrte Auflage. Von Dr. Paul Schultz, Privatdocent und Assistent am Kgl. Physiologischen Institut der Universität, Berlin. Berlin: S. Karger, 1901.

The very modest pretensions set forth by the author in his preface are more than justified by the little book he has produced. There is a perfectly legitimate field for such concentrated textbooks and they are not to be criticised on the score of incompleteness any more than is a school dictionary, for example; and so long as they are regarded by their users simply as adjuncts and keys, as it were, to the larger works, and not as short cuts to knowledge, they may be held to serve a useful purpose. The author has confined himself strictly to the true scope of a compend and, without indulging any tendency to theorization, has given the essentials of his subject in a simple and concise way. The letter press is aided by a moderate number of diagrams, and a useful set of physiological tables is appended.

Municipal Sanitation in the United States. By Charles V. Chapin, M.D., Superintendent of Health of the City of Providence. Providence: Snow & Farnham, 1901.

This large volume is a mine of information upon municipal sanitation in the United States, and its author has evidently been to great pains in collecting his material. Every subject closely or remotely related to sanitation receives attention, and the information is of the most detailed kind. We are able to learn from the book how every sanitary problem is solved in almost every city in the country. Chapters are devoted to nuisances, plumbing, water supply, the examination and care of food products, the control of communicable diseases, and refuse disposal. Naturally the last two subjects occupy a great proportion of the space, and what is said on each subject is valuable. Much statistical information is also given. An appendix is added which shows facsimiles of the various blanks and documents used in different towns, and which also contains copies of various health regulations. The volume is an excellent work of reference for the practical sanitarian.

A Treatise on Orthopædic Surgery. By Royal Whitman, M.D., Chief of the Orthopædic Department in the Vanderbilt Clinic in the College of Physicians and Surgeons of Columbia University, Adjunct Professor of Surgery in the N. Y. Polyclinic, etc., etc. Illustrated with four hundred and forty-seven engravings. Philadelphia and New York: Lea Brothers & Co., 1901.

This new work on orthopedic surgery is a reference textbook which aims to place the subject before the reader in a concise and comprehensive manner. The author has begun his work with a consideration of the pathological conditions of the spine which are seen usually by the orthopedist and which form such an important fraction of his cases. The treatment and sequelæ of Pott's disease are carefully considered and elucidated by numerous illustrations, in a way to make these chapters a valuable adjunct to clinical teaching. Hip-disease, its pathology and treatment, is discussed in all its phases, and the relative value of the different plans of treatment is considered. The remarks upon the operative treatment of abscess in connection with hip-disease are well worth reading. A number of pages is devoted to disease of other joints, such as the knee, ankle, and wrist, but disease of these joints is more amenable to general surgical treatment than to that called orthopedic. To deformities of the foot are devoted several of the most important chapters in the book, and the various forms of club-foot are described and commented upon. The author describes all methods, but the operative treatment of the various forms of talipes is so important that it would have been better to have given it more prominence, and to have described more fully the operative detail. The author has drawn his material from an enormously rich source, and has exercised judicious selection, so that he is able to place before his readers examples of all the conditions which the orthopedist will meet, and he has furthermore called photography largely to his aid in making his illustrations which are many and excellent. The volume should have a warm reception and will no doubt prove popular.

Die Chronische Gonorrhöe der männlichen Harnröhre. Von Dr. F. M. Oberlaender, Dresden, und Professor A. Kollmann, Leipzig. Leipzig: Georg Thieme, 1901.

While literature on chronic gonorrhœa has, in the past ten years, assumed prodigious dimensions, it has been but commensurate with increasing comprehension of the importance of the subject. Much of this literature is of genuine value to the profession, but most of the excellent contributions are either scattered in journals or made parts of large collective volumes, which are inaccessible to physicians at times when they are most needed. When, however, two acknowledged masters of the subject combine in one work, all that modern science demands of the diagnostician, and the therapeutist requires for the examination and treatment of chronic gonorrhœa, the medical profession is warranted in congratulating itself. Aside from its value as a work of instruction, the terse form in which the book is written, makes it an invaluable one for ready reference. It is a matter of regret that this first volume, which has just appeared, has not been provided with an alphabetical index. The list of contents, however, at the beginning of work in great manner supplants this, giving, as it does, under each chapter-title, an excellent synopsis of the subjects discussed therein. The authors make clear the exact principles upon which the location and character of pathological changes in the urethra and its adnexa can be determined. They show how a precise diagnosis is obtained by the urethroscope and the microscope, and they detail the bases upon which rational instrumental treatment must follow. Chapter I. (Anatomy of the Urethra) explains that, when at rest, the urinary channel has almost no lumen; one is formed only when urine, semen, or instruments separate its mucous walls. The form of the urethra varies considerably at different points and it is very dilatable. Its expansibility varies materially in regions and in individuals. Chapter II. is devoted to the gonococcus. The various manners of staining are so fully described that an error of technique therein becomes impossible. Its form, size, grouping, and situations are carefully detailed, as are the methods of culture, the biology of cultures, and inoculation. Chapter III. discusses acute gonorrhœa sufficiently for a foundation to the understanding of chronic gonorrhœa. Stress is laid upon the fact that an apparent absence of gonococci, even for a prolonged period, does not warrant declaring that infectiousness has ceased. This outcome is determinable only after all the tests, including urethroscopy, have been employed. Chapter IV. is devoted to the pathological anatomy of chronic gonorrhœa. Chapter V. discusses the discharge. It shows that not rarely the absence of visible discharge and the absence of visible filaments in the urine do not prove the absence of urethral infection. In this chapter the various macroscopic tests of urine are described. Chapter VI., on the disturbances of sensation, shows that these vary considerably and oftentimes bear no relation to the intensity of the disease. The functional symptoms, and the diagnostic value of each, are freely discussed. Chapter VII. treats of inspection and palpation of the genitalia, and the use of exploratory instruments, but warns the student against the insufficiency of these methods of diagnosis. In Chapter VIII. urethroscopy is most fully and satisfactorily discussed. Over one hundred pages are devoted to the technique of this invaluable diagnostic means, without which no chronic gonorrhœa can be intelligently treated. Throughout, the subject of chronic gonorrhœa is presented by the authors in such a practical, reasonable form that an English translation of this work would be exceedingly desirable.

Society Reports.

CANADIAN MEDICAL ASSOCIATION.

Thirty-fourth Annual Meeting, Held at Winnipeg, Manitoba, August 28, 29, and 30, 1901.

(Special Report to the MEDICAL RECORD.)

First Day—Thursday, August 28.

DR. H. H. CHOWN OF WINNIPEG, PRESIDENT, IN THE CHAIR.

Address of Welcome.—In the absence of Chief Justice Killam, Dr. J. H. O'DONNELL, one of the oldest practitioners in the West, delivered the address of welcome. He referred to the conditions present in 1880 when Winnipeg was an outpost of civilization, and spoke of Dr. Cowan, Dr. Curtis J. Bird, Dr. Beddon, and Dr. Bund, who were already in the West when Dr. O'Donnell moved there in 1869.

Dr. CHOWN briefly thanked the association for the honor they had conferred upon him at the meeting in Ottawa one year ago.

Dr. STARR, the Secretary, presented his annual report. It referred to the meeting at Ottawa last year, to the attendance of 153 members, which was an increase over former meetings in that city; to Dominion Registration, and to the formation of a Physicians' Protective Association.

Dr. Edebohls of New York and Dr. Sutton of Pittsburg were welcomed to the Convention and requested to participate in the discussions.

The Question of Medical Defence.—This was introduced by Dr. RUSSELL THOMAS of Lennoxville, Que., who had been delegated by the St. Francis District Association to present this subject to the Canadian Medical Association. He made a strong plea for the formation of a Medical Defence Union, and thought that all were agreed on the necessity for such. He supported his contentions by citing two or three cases already well known to medical practitioners in Canada, and after showing that such defence unions were a success in England, he concluded by outlining the plan of medical defence already in vogue and supported by the St. Francis District Medical Association, which he was authorized and prepared to hand over entire to the Canadian Medical Association. The discussion of this important matter was deferred until later on in the session.

Address in Medicine.—Dr. J. R. JONES of Winnipeg delivered this address, taking for his subject "The Question of Medical Education." In opening his remarks he referred to the unsolved problems of medical education, the importance of which were especially manifest in view of the establishment of a Dominion Medical Board. Uniform or equivalent curricula, he thought, would greatly facilitate paving the way for the accomplishment of this object. He thought that the great aim of the Canadian Medical Association should be to create a Dominion Medical Board upon such a sound and enduring basis that the qualifications could be registered in every province of the Dominion. They should not only be Canadian but Imperial, capable of registration in Great and Greater Britain. There should be no special education for the profession of medicine, and the defect in the preliminary education of medical students should be corrected. The standard is not high enough. Many students came into the medical college, their minds totally unprepared, undisciplined, not competent to engage in the different studies of a profession with advantage. Dr. Jones would not eliminate Latin, but would go a step further and advocate a more general knowledge of Greek, as Greek was *par excellence* the language of science. He quoted from two eminent authorities, who favor the retaining of "classical education" as training for professional studies—Dr. Alexander Hill, a medical man and master of Downing College, Cambridge, and Professor Jebb of Dublin. He referred to medical matriculation examinations and deplored the lamentable defects in the English paper, the most neglected subject in our primary schools. From an experience of many years as an examiner at the University of Manitoba, Dr. Jones has concluded that the teaching of English takes a very subordinate position in our schools. The defect was a universal one; and it was obvious that if English should become a prominent subject of medical matriculation examination every student ought to be able to express his thoughts coherently and intelligently. The didactic lecture came in for adverse criticism, and defects and useless wastes of time which could be more profitably employed were pointed out. Persistent work in the dissecting room under the guidance of an experienced demonstrator who will describe, discuss, and constantly orally examine the student is a rational and effective method of teaching anatomy. Medical jurisprudence and sanitary science were not properly taught.

Dr. Jones supported the "case" method of teaching; and from personal experience he favors the English system of clinical clerkships and dresserships as the most feasible, practical, and thorough for the development of medical teachings. He referred to the question of Dominion registration and pointed out two serious objections to Dr. Roddick's Bill: First—the great number of the representatives of the Council, entailing expenses beyond at least our immediate resources; and, second, the fact that one of the contracting parties to Dominion Registration may secede, and the elaborate fabric, the work of many years, tumble to the ground. The able paper of Dr. Jones was received with much gratification by the association.

Dr. R. B. NEVITT, Dean of the Woman's Medical College, Toronto, in moving a vote of thanks to Dr. Jones for his able paper, stated that he had placed his finger on the weak point of medical education. Dr. S. J. Tunstall of Vancouver seconded the motion for the vote of thanks and also congratulated Dr. Jones for the excellent manner in which he presented his subject.

Dominion Registration.—Dr. T. G. RODDICK of Montreal, who had so long and so ably advocated this much-to-be-desired measure, delivered a stirring address on the subject, ably reviewing the subject of Inter-Provincial Registration from the time of its inception to the introduction of his bill at the last session of the House of Commons. The special committee appointed on this subject had not yet reported, so the discussion was postponed until the committee had a chance to meet and report later on in the session. Dr. Roddick now seems to hold to the opinion that the suggestion of Dr. Britton of Toronto, that representation by population, for Ontario at least, would be advisable.

Infectious Pneumonia.—Dr. W. S. MUIR of Truro, Nova Scotia, read this paper. He reported four cases, all of which had occurred between the 1st and the 13th of April of this year, in the same house and in the same family. The first occurred in a child of ten years, the disease terminating by crisis on the sixth day, the child making a good recovery. A sister, aged fourteen, contracted the disease; terminated by crisis on the ninth day, but followed two days after by left-sided pleuro-pneumonia. This proved fatal. The third occurred in a sister, fifteen years of age, beginning with a pain on the left side, and terminated on the tenth day by crisis and recovery. Number four developed pneumonia, but recovery was quick, the patient being about in two weeks. There was no influenza in the town at the time. Dr. Muir spoke of the organism of pneumonia, its cultivation, and its detection.

President's Address.—Dr. CHOWN, in beginning his address, said that, as this was the first time that the Canadian Medical Association had met in Manitoba, he would refer briefly to the future of that province. Although less than

ten per cent of the arable land was under cultivation, Manitoba's farmers would this year have a crop estimated at 85,000,000 bushels of grain. He then referred to the work performed in Winnipeg for the purpose of making that city a healthy one, and in spite of the level nature of the land, an excellent system of sewers had been introduced through all the streets; and efficient arrangements had been made for regular flushing of the sewers by means of tilting basins at the upper end of each of the main sewers. As Winnipeg has two rivers at her door, the problem of removing sewage was easily and safely solved. Dr. Chown then referred to the water supply, and said that the people of Winnipeg enjoyed as pure water as could be found in the world. An examination of the city water would show that there was in it only nine to thirty colonies of bacteria. The water is taken from an artesian well seventeen feet in diameter and forty-eight feet deep, and although they have been pumping for months a supply of from two million to three million gallons per day, there is not the slightest evidence of any diminution of the amount flowing in. This well is supposed to tap an underground passage which runs from Lake Manitoba, and as this lake is 130 miles long, the supply is inexhaustible. The underlying rock formation in that section of Manitoba is a magnesia limestone, and, consequently, the water contains a large amount of the carbonate of lime and of magnesia, and is too hard for satisfactory use in boilers and hot-water appliances. This is overcome by using Clarke's method of softening by precipitation of these carbonates through the action of lime water; and the softening plant is unique on this side of the Atlantic. Dr. Chown then referred to the question of tuberculosis, and thought that Koch's tentative denial of the oneness of tuberculosis of man and tuberculosis of cattle still needs the proof of non-inoculability from cattle to man. He instanced cases of young farmers free from tuberculous taint living in newly built houses, harboring no bacilli, and separated by long distances from their neighbors, in whom tuberculosis constantly makes its appearance; and we have here an experiment on a wide scale; and if you can eliminate heredity, house infection, and contagion from other cases, to what cause can you ascribe the origin of these outbreaks? Medical education, the plan of Dominion registration as introduced by Dr. Roddick, malarial fever, proprietary drugs, the progress in surgery, and the future of bacteriology and hæmatology were subjects ably dealt with. In concluding, Dr. Chown said that a duty rests upon the medical profession to get at the true cause of all forms of disease and rescue the public from both the honest fanatic and the ignorant pretender by doing not only all what these claim, but doing more and doing it better

Epidemic Cerebrospinal Meningitis.—Dr. James McKenty of Gretna, Manitoba, presented this paper, which gave an account of an epidemic occurring in North Dakota during the winter and spring of 1893. It occurred within an area extending fifty miles from east to west and twenty miles from north to south, and was comparatively definitely limited. About seventy persons were seriously ill, and almost as many others suffered from mild manifestations of the disease. Of the seventy cases, twenty-five ended fatally—a mortality of about thirty-five per cent. In the practice of Dr McKenty there occurred some thirty cases, a brief record of twenty-two of these being kept. The average age was seventeen years; the youngest fifteen months; the oldest thirty-eight years. The duration of the disease extended from twelve hours to fifteen weeks. No post mortem was made in any case. Dr. McKenty then described in detail the clinical aspects of several cases.

Splenic Anæmia. Dr A. J. Macdonnell of Winnipeg contributed this paper with the history of the case. This was an exceedingly rare disease. In 1898 the number of cases recorded did not exceed thirty, but since that time there have been fifty additional cases reported. R. N., aged twenty-seven years; environment good; has never had malaria; habits and mode of life good; positively never had syphilis. The present illness began in August, 1899. He complained of heaviness on the right side, with a feeling of fulness and weight. In January, 1900, he gave up work on account of muscular weakness. There was no vomiting at any time. The patient consulted Dr. Macdonnell in March, 1900, walking into his office with considerable difficulty. There was no enlargement of the lymphatic glands. Enlargement of the stomach could never be made out by percussion or palpation. The liver dulness was practically normal, and there was no jaundice or pain in the liver region. The patient succumbed to the disease, but no post mortem was held. Another case occurring in a patient, aged seventeen, was reported. Dr. Bell made a blood-count in this case, which at different times ranged from 3,400,000 to 3,600,000 red blood cells, with 7,602 leucocytes. In this case all the other organs were normal; and there seemed to be no predisposing cause in this case. Dr. Macdonnell stated that only ten autopsies had been made on people dying from this disease. He referred to the conditions found post mortem in these cases. The treatment for these cases was stated to be rest, diet, and vigorous doses of arsenic. The mortality is set down at twenty per cent. As far as operation is concerned, physicians will not be satisfied until it is clear that the patient recovers from the operation as well as from the disease. If we are sure of our diagnosis, then surgical intervention is deemed advisable.

Physical Development.—Dr. J. N. Hutchison of Winnipeg read a carefully prepared paper on this subject. The paper did not deal with anything new, but called attention to and emphasized certain facts of considerable importance. He considered that children were sent to school at too early an age, and as a result there was danger of brain overwork. He insisted upon the necessity of having healthy parents and deplored the system of education which develops the mind at the expense of the body. He was an advocate of periodical lectures by duly qualified physicians to separate classes of boys and girls on the subject of sex; but the primary responsibility in this matter he placed upon the parents. There would be real progress in the prevention of tuberculosis when people subject to the disease recognize that they should not marry. The paper, which was listened to with close attention, closed with a reference to the problems of those unfortunates who are neither mentally nor physically qualified for the duties of life.

Report of Cases Treated with Superheated Dry Air.—Dr. W. H. Pepler of Toronto introduced this subject in a paper which cited his experience and observations in the treatment of certain cases by this plan or process. He briefly described the apparatus and the method of treatment. It only takes twenty minutes to reach a heat of 300° F. The average duration of the application of the heat is forty-five minutes. The physiological and therapeutical effects noticed were referred to, as dilatations of blood vessels, etc. He administers the treatment one hour after meal-time with due regard that there shall be as little as possible excitement and exertion. He has not seen any ill effects from the treatment. He first gave notes of the case of a patient, a man aged thirty-five years, who had suffered for some time from varicose ulcer of the right leg, with considerable pain. This patient had a treatment of thirty-five minutes' duration, and was able to walk home with very little discomfort. After three times in ten days the ulcer was very much reduced in size. The second case was a patient, twenty-two years of age, who had been troubled with rheumatism for two years past. A temperature of 320° was employed with good satisfaction. Several other cases of rheumatism and eczema were reported. The

treatment in each case proved highly satisfactory, patients never complaining of any discomforts, and all expressing satisfaction with the treatment. Dr Pepler subjects a considerable portion of the patient's body from a temperature of 280° to 320° F. The results are often not apparent for some time after treatment

Dr. McAdam of Battleford asked Dr. Pepler if he had ever tried the treatment with high temperature where he had any doubts of the condition of the heart.

Dr. MacDonald of Brandon referred to a case which had come under his observation in which there was heart trouble. Perspiration occurred freely, but with no effect in a depressing way upon the circulation. Treatment in this case was continued for two weeks, but he had never determined that there had been any effect upon the heart, although there was a small heart lesion at the time.

Dr. Pepler in reply said he could not speak personally as to any deleterious results from weak heart. Of course, there were many cases reported where heart trouble was present. He personally had never noticed any heart or head symptoms in his cases. He thought with care there would be no bad results.

Orthopedic Treatment of Deformities and Disabilities Resulting from Diseases of the Nervous System.—Dr B E McKenzie of Toronto read this paper, making special reference to tendon transplantation. He spoke of disabilities and deformities resulting from paralysis, some of which were commonly regarded as hopeless; but the conditions of a great majority of them were remediable and should receive a considerable amount of attention. He was at some pains to explain the respective motion of joints, particularly the ankle joint and knee joint, especially calling attention to the normal conditions of equilibrium, and then showed how the muscles of some of the groups at times become paralyzed and the balance and equilibrium thereby destroyed. Mechanical treatment was often necessary and often efficacious as well; massage and electricity had their respective places, but he had made particular reference to the method of treatment that had been in vogue for twenty years and had been introduced on this continent by Dr. Parish of Philadelphia. He went carefully into an explanation as to how muscles can be transferred from their usual point of action, and then he gave an account of several cases in which he had successfully accomplished this. In his opinion amputation of a limb because of apparent disability should seldom or never be resorted to. He disapproved of jackets in treatment of curvature of the spine.

Dr. Clarence Starr of Toronto said that the subject was of great interest to him, as he was interested pretty largely upon the same lines of surgery. Dr. McKenzie had indicated a large number of cases of paralyses which can be wonderfully helped by operative procedures. He thought that Dr. Bowlby of Boston deserved a great deal of credit for the work he has performed in this connection.

Dr. H. B. Small of Ottawa referred to a case Dr. McKenzie had operated on. In this case previous to operation, the boy had great difficulty in arising from the sitting posture, and when walking he had to rest every few yards. After the operation he was very much improved, and when Dr. Small last saw him about a week ago he could walk very easily, and never had to support himself. The improvement during the last four or five weeks was especially very marked.

Second Day—Friday, August 29.

Mild Smallpox.—Dr G A. Kennedy of McLeod, Alberta, presented this paper. It dealt with the recent outbreak of the disease in the Northwest Territories, an outbreak which was widespread and which had existed for some time before its true nature was recognized. Dr Patterson, Quarantine Officer for the Dominion Government, was satisfied that there had been 1,500 cases. A noteworthy fact was that the greatest number of cases occurred among the French halfbreeds who had never been vaccinated, and, further, Indians on reserves had not suffered to any great extent, as annual vaccination is the rule. Not one case was seen or heard of among Galicians, Doukhabors, or Roumanians, which was due to the fact that compulsory vaccination was the rule in youth and then they had been revaccinated on their recent passage across the Atlantic and at Halifax. Fifty per cent. of all cases were extremely mild in character; forty per cent. were cases of typical variolod; ten per cent. were severe, almost confluent. The mortality was slight, only thirteen deaths occurring; and the disease prevailed fully as much among adults as among children.

Dr. Muir of Truor, Nova Scotia, discussed the merits of the different vaccines on the market, and the paper was further discussed by Dr. MacDonald of Brandon, Dr. Inglis of Winnipeg, Dr. D. H. Wilson of Vancouver, and Dr. Montizambert of Ottawa. The latter considered it would be unfortunate if the impression went abroad that any doubt existed in the minds of the members of the Canadian Medical Association as to the true nature of the disease which had been epidemic for some years. He considered the facts presented in Dr Kennedy's paper relating to Doukhabors and Galicians were perhaps the most valuable portion of it

At the close of this discussion the following resolution was moved by Dr. R. S. Thornton, seconded by Dr. J. L. Bray, and unanimously adopted: "*Resolved*, That in view of the general prevalence of smallpox throughout the continent, this association desires to urge upon the profession and the public generally the necessity of vaccination and revaccination."

Chronic Ulceration of the Stomach, Simulating Cancerous Disease.—Dr. J F W Ross of Toronto reported this case, in which he performed gastroenterostomy with the Murphy button. This occurred in a woman twenty years of age, the condition of whose stomach had been bad for three years. She was a nurse in the training school of a hospital. As her gastric condition grew gradually worse and worse, Dr. Ross was asked to see the patient by Dr. E. B O'Reilly of Hamilton, in December, 1899. He found her emaciated with the opium habit already formed. In January, 1900, he again saw her, with Dr. Griffin of Hamilton. At this time rectal alimentation was being persevered in with considerable benefit. In March, 1900, she was discharged from the hospital and remained well for two weeks. As soon as food passed into the stomach great rigidity of the right rectus muscle was noted. When the patient came under Dr. Ross's attention she weighed about seventy-five pounds. As malignant disease of the stomach is rare at this age of life, it was difficult to diagnose the tumor as such, and the symptoms pointed to the pyloric end of the stomach. It was not possible to say whether cancerous or not. The symptoms pointed to the presence of ulcer, but the thickening easily made out led to the belief that malignant disease had been grafted on to the ulceration. Some dilatation also could be made out, but the rhythmic muscle waves so characteristic of pyloric obstruction could not be found; but a large growth was found at the pyloric end. The case was looked upon as hopeless, and decision was arrived at not to remove the growth, but to give temporary relief by gastroenterostomy. This was done and the patient made an uninterrupted convalescence. Eleven months after the operation the patient weighed 140 pounds and looked the picture of health. On examination of the abdomen no mass could be felt, and the patient was not suffering from any gastric symptoms at all. Dr. Ross then went into the literature on the subject, quoting Fagge, Sydney Martin, Monihan, and Mayo Robson.

Dr. Lapthorn Smith of Montreal said that the case was especially interesting to him, but rather from the general practitioner's point of view. He believed that no case of cancer of the stomach ever begins as cancer of the

stomach. First, there is some sort of irritation of the mucous membrane, and this irritation finally becomes a chronic ulcer, upon which the germ of cancer is engrafted or whatever it is which is the essential constituent of the cancerous process.

Some Forms of Hyperacidity and Their Treatment.—Dr. C. F. MARTIN of Montreal presented notes of some interest, judging from the results of systematic examination of the gastric contents. The unfortunate general employment of the term dyspepsia is responsible for the disregard of this condition. In the case of organic disease producing excessive secretion the diagnosis is often difficult. He gave the history of two cases in illustration, the second being an individual, forty-five years of age, who gave the usual history of having been ill for six months. There was no obstruction of the pylorus, but simple dilatation, and the diagnosis was hyperchlorhydria with simple dilatation of the stomach. He also referred to the medical treatment following gastroenterostomy.

Medical Defence.—The report of the Committee on Medical Defence was then presented by W. S. MUIR of Truro, Nova Scotia. It reported favorably on the formation of a medical union, and the organization thereof was immediately perfected. It will be known as the Medical Protective Association, will be incorporated, and will have for its object the protection of the character and interests of medical practitioners in Canada. It will further promote honorable practice, will aid in suppressing or prosecuting unauthorized practitioners, and will seek to advise and defend or assist in defending members in cases where proceedings involving questions of professional principle or otherwise are brought against them and other like matters. Dr. R. W. Powell of Ottawa was elected president; Dr. McKinnon of Ottawa secretary, and Dr. James Grant, Jr. of Ottawa treasurer.

Report of Committee on Dominion Registration.—It is proposed to secure an amendment to the B. N. A. act, or to take advantage of section 91 of that act and under it obtain legislation from the Dominion Parliament, by which the profession in Canada may form a Dominion Council, and which can be supplemented by legislation by the various provinces recognizing any certificate of standing issued by the Dominion Council as entitling a holder to practise in such provinces. Dr. Muir approved of Dominion registration, and spoke for the Province of Nova Scotia. Dr. Jones voiced the sentiments of the profession for Manitoba. Drs. A. A. MacDonald and J. L. Bray endorsed the scheme for Ontario. Dr. Russell Thomas spoke for Quebec. Dr. Christie said that New Brunswick was in favor of Dominion registration. Dr. Lafferty said the Northwest Territories were favorable.

Cancer of the Uterus, with Lantern Demonstrations.—Dr. THOS. S. CULLEN made an interesting demonstration of this condition. In introducing Dr. Cullen, Dr. Chown spoke of him as a young Canadian who had gone wrong in having removed to the United States and having never returned. Dr. Cullen showed a large number of slides from microscopic examinations of tissues, each view being lucidly explained by the demonstrator. At the close of his excellent demonstration Dr. Cullen was accorded a hearty and unanimous vote of thanks, moved by Dr. Eccles of London and seconded by Dr. Gray of Winnipeg.

Skin Diseases, with Lantern Demonstrations.—Dr. FRANCIS J. SHEPHERD of Montreal made another valuable demonstration. He first exhibited cases of blastomycetic dermatitis, and further spoke of a few cases which he had seen of this disease. Views were given also of cases after treatment with iodide of potassium. Some interesting views were those caused by drug eruptions, of which he showed two or three due to salicylate of sodium. In one of these, Dr. Shepherd said that the lesions first came out with large welts like those of urticaria. This is rather a rare form of drug eruption. It appeared after two doses of ten grains each of the drug. One patient almost died of acute laryngitis from the eruption in the throat. Other views shown were of papular purpura, which is generally associated with rheumatic attacks; psoriasis of the nails, *x*-ray burns as the result of one application, and several of smallpox, one showing pustules upon the palm of the hand; this was particularly interesting, as in adults one never sees chickenpox upon the palm of the hand, but smallpox invariably shows itself there. Views of feigned eruptions were also shown.

The Varieties and Distribution of Bacillus Diphtheriæ and Their Clinical Significance.—Dr. F. F. WESTBROOK of the University of Minnesota presented a paper on this subject, primarily from the laboratory point of view. He exhibited a carefully prepared chart showing in tabulated form the results of numerous examinations in schools, and stated the conclusions which he deducted from these facts. Formerly, it was believed that the bacillus remained localized at its point of entrance, but now within recent years, however, careful observations have showed that the toxins had been distributed throughout the body, and the bacillus itself found in organs far removed from the atrium. From evidences of 230 cases of diphtheria at autopsy, observers had called attention to the frequency with which the bacillus of diphtheria was found in the organs of the body. The bacillus and its toxins have been shown to be capable of producing lesions which differ greatly from each other, as in ulcerative endocarditis, meningitis, etc. In summarizing, Dr. Westbrook said where each school was reported, and where great care was taken in the isolation of clinical cases with typical form, the percentage was very small.

Removal of a Large Hairy Tumor from the Stomach.—Dr. H. A. BRUCE of Toronto reported this case. The subject was a woman aged twenty-six; she had been married six years and had two children. A lump was noticed in the abdomen two months previous to the birth of the last child. The patient had no symptoms. The lump was about five inches in width and it could be lifted forward. It reached to within three inches below the umbilicus. It gave the patient no special discomfort, there being absolutely no symptoms present. Dr. Bruce advised exploratory incision. This was done on July 22d at St. John's Hospital, Toronto. On opening the abdomen in the middle line, the spleen and kidneys were found in a normal condition, but there was a large mass in the neighborhood of the stomach. The surgeon could make out a mass lying free in the stomach, a portion extending through the pyloric end of the stomach. An incision was made into the stomach and the mass removed. After removing the mass of hair, the opening of the stomach was closed in the usual way. Hot salt solution was given for two hours, and nutrient enemata for six hours. Twenty-three hours after the operation sips of hot water were given by the mouth. Forty-eight hours after the operation the patient was given one-half an ounce of milk and lime water every hour. She left the hospital on the twentieth day. The tumor was entirely of hair, exactly the same color throughout and the same color as the hair on her head. It was about twenty-four inches in length, being about two inches in diameter at one end and gradually tapering to a point at the other; it weighed twenty-three ounces. Dr. Bruce considered this case rare, but offered no solution as to how the hair got into the stomach. There were no evidences of hysteria present in the patient.

Third Day—Saturday, August 31.

A Case of Transplantation of the Ureter for Cure of Uretero-Vaginal Fistula.—Dr. A. LAPTHORN SMITH of Montreal reported this case. It occurred in a married woman thirty-four years of age, who came to Dr. Smith on the 1st of July, 1901. During parturition, forceps was employed and the vagina was lacerated. Ever since there has been a constant flow of urine by the vagina. Operations for her relief had been performed in England without success. Dr. Smith had seen Sänger

perform an operation of this character in Leipsic when he was there three years ago, namely, to open the peritoneum running over the large vessels at the brim of the pelvis, feel for the artery, see the vein, and pick up the third tube, which was the ureter. The operation was done in the highest Trendelenburg posture. A very small incision was made in the peritoneum lining the pelvis in the line of the ureter, a silk ligature was passed around it and then the ureter was severed a little above the ligature. The end of the ureter was split open to a distance of a third of an inch. A slit was then made obliquely into the right upper corner of the bladder and the ureter stitched into it—the mucous membrane of the ureter to the mucous membrane of the bladder—with very fine chromicized catgut. This is the first time this operation has been done in Canada and Dr. Smith stated that not a drop of urine had passed through the fistula since.

Syphilis as Seen by the Ophthalmic Surgeon.—Dr. F. BULLER of Montreal in commencing his paper expressed the hope that it would elicit a little discussion. It often falls to the lot of the ophthalmic surgeon to discover the presence of active syphilitic virus where the disease had long since been considered cured or that the subject cherished the belief that there was no more to fear from it. The ophthalmic surgeon is scarcely, if ever, called upon to treat the disease in the primary stage. The largest share of his work is in connection with the tertiary period, and in this class of cases the disease has been apparently cured for a long period of time. Dr. Buller considered that the time at which the syphilitic lesion makes its appearance is always a very important element in the diagnosis. Discussing medication the speaker did not believe that the protiodide of mercury, at least as ordinarily administered, is a reliable anti-syphilitic. He appeared to favor the inunction method first, and then the administration of grey powder.

The Present Outbreak of Smallpox in America.—Dr H. M. BRACKEN of Minnesota in this paper outlined the origin and traced the course of many outbreaks in various parts of the State of Minnesota. A porter on the Great Northern Railway, who arrived in St. Paul in March, 1899, was mentioned as the source of the outbreak. He was supposed to have contracted the disease in Seattle and when told that he had smallpox he said that if so there was plenty of the same disease where he came from. Other epidemics were spoken of in various parts of Minnesota with a total of 9,129 cases and the disease has still many centers in that State. It is impossible to locate positively the source of the present widespread epidemic farther than that it spread from the Southern and Southwestern States into North Dakota, Minnesota, Nebraska, Montana, and Texas. Dr. Bracken showed that returning soldiers from the Philippines were not responsible for its introduction. He suggested that it was probably imported into the United States by Cuban refugees before war broke out between that country and Spain. Vaccine, he said, was frequently spoilt by not being kept in proper temperatures as it was frequently being shipped in cans which were too hot and subsequently kept in warm offices. The Health Commissioner of Minneapolis kept all his vaccine in an ice-box, but, of course, not frozen, and had obtained good results. Replying to a question in regard to isolation Dr. Bracken favored eighteen days' quarantine.

The Necessity of a Recognition and Isolation of Trachomatous Patients in Canada.—In the absence of Dr W. GORDON M. BYERS of Montreal, Dr. C F. MARTIN of the same city read this paper. The paper recited the history of a young girl from Glengary County, Ontario, who came to the clinic at the Royal Victoria Hospital, Montreal, with a most intense condition of granular lids. She had been unable to open her eyes properly for months past and her vision was reduced to the counting of fingers. The seriousness of her disease had not been recognized at home, as she mixed freely with other members of the community. Another case was referred to in the County of Leeds, and in this case as well no precautions had ever been taken to prevent the spread of the disease. Dr. Byers believes that there are many unrecognized and untreated cases scattered here and there throughout the Dominion. The disease is said to be prevalent in districts of Manitoba and certain centers in the eastern counties of Ontario and others in Quebec. The trachoma problem has had to be faced by one Government in Europe and the matter has been brought to the attention of the Dominion Government, which has not yet taken any action in the matter. Dr. Montizambert stated that the question of exclusion of trachomatous immigrants had been under consideration by the Government for some time. He considered these people somewhat undesirable immigrants

A Few Notes on the Treatment of Typhoid Fever.—Dr. J. L. BRAY of Chatham discussed this subject under medicinal, dietetic, and hygienic headings. The first he thought might be eliminated except in cases where complications arise and he thought a certain amount of medicinal treatment useful during the initiatory stages. He was in the habit of employing calomel. Tympanites could be avoided to a great extent by a proper diet. In feeding he now gives very little milk, but that little always peptonized. He believes in making the patient drink two or three quarts of pure water in the twenty-four hours. Albumen water with sugar may be given from the first; after the first two weeks he gives liquid peptonoids, or some of the numerous preparations of beef, jellies, mutton broth, or a soft boiled egg. As regards the hygienic treatment, the bedding and the night clothes should be changed daily. The room should be kept thoroughly ventilated, admitting plenty of fresh air and sunshine. The patient should be sponged frequently with tepid water and you get just as good results from tepid water as from sponging with very cold water or the cold bath, and it is not so distasteful to most patients. In hospital practice, Dr. Bray used the electric fan after using the tepid water. He has found this plan very satisfactory, especially in young and sensitive children.

Dr. RUSSELL THOMAS said that he had found the ice-cap beneficial, that it did not disturb the patient and had a decided effect in reducing the temperature.

Address in Surgery.—Dr. O. M. JONES of Victoria, B. C., opened his address with a reference to surgical diseases in Western Canada as compared with those in the East and stated that he had often found Western sufferers more impatient, which often demands severer methods. He illustrated this by citing a humerous incident. A lodging-house keeper, on learning that one of her lodgers was to have an operation performed on a Wednesday, wrote to the surgeon asking that it might be postponed until Friday, as her daughter was to be married on Thursday, and they didn't want the corpse home until after the wedding. The address dealt mainly with surgery to the stomach and related the deductions Dr. Jones has arrived at from his own experience of twenty-six cases. His first operation upon the stomach was in 1893—a case of pyloric obstruction in a wiry woman. Senn's plates were used. This patient died in three days, the result not being encouraging, and Dr. Jones attributed the failure to the use of catgut instead of silk sutures. The introduction of Senn's plates and the Murphy button gave a great interest to intestinal surgery, as before 1890 operations on the intestines were rare. He discussed the preparation for operation, and first spoke of gastrostomy, an operation which he had performed five times for ulcer of the œsophagus. In four of the cases the operation was performed with very excellent results. He then discussed the

class of cases in which pylorectomy is indicated, and said that rapidity of operation in these cases is the very important factor, prolonged operation has generally proved fatal. A suitable case should be cancer of the pylorus. The time occupied in performing the operation is not great. In one of his cases he performed posterior gastroenterostomy. This patient still lives and it is now nearly three years since the operation. Gastroenterostomy was next discussed. This Dr Jones considered the most important and most interesting part of the whole subject. It is the most frequent and the most useful and the simplest of all the operations performed upon the stomach. It is performed for pyloric cancer, ulcer, and stenosis and for gastric ulcer, dilatation, etc. Nothing can be simpler than this operation performed with the Murphy button. Dr. Jones has used it in fourteen cases and in only one case was there any trouble. In two of his cases, which died from shock, he examined one and found perfect union. He has found that the passage of the button has taken from fourteen days to four months; and in several cases he has not been able to obtain the button. A recital of several cases followed, which proved very interesting. Dr. Jones closed his paper with a few words on perforating duodenal ulcer.

Dr. F. J. SHEPHERD of Montreal proposed a vote of thanks. Dr A. A. MacDonald of Toronto seconded this; Sir James Grant of Ottawa supported the motion, which was unanimously passed by the association.

A Surgical Procedure for the Relief of Ovarian-Tension Pain.—Dr. HENRY HOWITT of Guelph, Ont., read this paper. Pain, he said, is frequently, if not usually, caused by tension on some nerve filament. The operation Dr. Howitt employs is quite simple. The ovary is exposed and then a number of cross-sections are quickly made through the tense capsule in such a manner as to divide it. Then the larger Graffian follicles are opened. They are merely touched with carbolic acid. If the capsule is thickened a portion should be removed. Hemorrhage has never been troublesome. Adhesions give rise to no complications. Dr. Howitt recited the histories of two or three cases in support of the operation.

Dr LAPTHORN SMITH stated that he had never heard of this operation before, and considered that it was original with Dr. Howitt.

Symposium of Tuberculosis.—Professor RUSSELL of the University of Wisconsin introduced this subject in a careful, yet exhaustive paper on human and bovine tuberculosis and their inter-relation. The importance of any phase of investigation relating to tuberculosis and its relation to milk is unquestioned in these latter days when the general public is beginning to appreciate, for the first time, the magnitude of the problem that confronts them in attempting to lessen the ravages of the "great white scourge" of the human race. This subject may be approached from two points of view (1) from the standpoint of animal industry, and (2) from that of public health.

Bovine Tuberculosis. The rapid extension of the disease among cattle within the last few decades has forced upon breeders and dairymen the necessity of considering this subject, whether they desire it or not. It is customary in many quarters, even yet, to decry all consideration of this matter as unnecessary, inexpedient, and harmful to the dairy interests. But, as is too frequently the case, the motive for such action rests upon a financial foundation, and many breeders are averse to a calm, judicious discussion of the matter simply because it may mean financial loss to them. Since the introduction of the tuberculin test as an aid in the diagnosis of the disease in cattle, it has been positively determined that the malady, at least in its incipient form, is very much wider spread than was formerly supposed, but it by no means follows that all animals that react to the tuberculin test are actually in a condition in which they or their products are dangerous to man and beast.

The slow, insidious nature of the disease that characterizes it in the human is also to be found in the cattle, and not infrequently an animal may be infected with the seeds of the disease for a considerable time—even a year or so—without showing in any degree physical symptoms that are manifest to even the animal expert. Such animals are not diseased in the ordinary meaning of the term, *i. e.* they are not capable of transmitting the disease, either directly or indirectly, through their milk or meat. The affection in such cases is latent, generally confined to various lymphatic glands, but animals so affected are, however, potentially dangerous, for the latency of the disease may be overcome through the operation of various factors, and the chronic type may thus be awakened into an acute phase. It is in this way that the disease spreads slowly and unperceived through a herd. Before it has made such inroads as to cause actual death of any considerable number of animals, many more have acquired the trouble, at least in the earlier phases. Necessity of controlling its spread and eradicating it is evident for the sake of the herd itself, if from no other point of view. Successful animal industry, especially with cattle, requires that herds shall be kept free from all taint of this disease. As to treating milk, Professor Russell said Pasteurization and sterilization were the two best forms of applying heat to destroy the organism. He recommended the rotatory Pasteurizing machine, one of which has been used in Winnipeg for some years, as the best method of removing organisms from milk.

Dr. GOOD of Winnipeg in discussing the paper said that it afforded him some relief to learn that milk is not so dangerous after all. He stated that he had been avoiding milk and all organic fluid for the past year or two, but he was glad to know that he could now go back to its use with the same freedom as in its younger days. He then moved a vote of thanks to Professor Russell, seconded by Dr. McArthur, which was unanimously adopted.

Sanatorium Treatment of Tuberculosis.—Dr. A. J. RICHER of Montreal contributed a paper on this subject. This treatment had been introduced by Dr. Trudeau in America under great difficulties, and at the present time this distinguished scientist was able to house and treat over one hundred individuals in his institution. According to Dr Richer, the treatment is made up of rest, outdoor life, over-feeding, and medical supervision. This latter was described as the keynote to success in phthisical treatment. The importance of over-feeding was also emphasized.

Early Diagnosis of Tuberculosis.—Dr GILBERT GORDON of Toronto read a paper on the etiology and the early diagnosis of pulmonary tuberculosis. He spoke of the early stages of the disease, and thought that we ought to be able to diagnose it before the appearance of the bacilli in the sputum. Direct inheritance he considers very rare. The inhalation of dried sputum is the most direct cause. Dr. Gordon considered that we are woefully behind in Canada in fighting this plague, and more money should be spent by governments and philanthropic individuals in fighting this disease. He went carefully into the symptoms of the pre-tubercular stage and considered that a persistent cough was a very dangerous symptom.

An important discussion took place upon this topic. Dr Lafferty warned the profession in Ontario against sending advanced cases of tuberculosis to the North-West Territory. Dr. Barrick of Toronto pointed out that Ontario was leading in regard to the treatment of tuberculosis, and he hoped to see the sanatorium brought with a wide open door to all conditions of life. Dr Brett of Banff suggested that the association should pass a resolution pointing out to the Parliament of Canada the neces-

sity of providing for the establishment of sanatoria for the benefit of the community.

Election of Officers.—The report of the Nominating Committee was presented by Dr. W. S. Muir, Truro, N. S., who expressed regret at having to accept the resignation of their General Secretary, Dr. F. N. G. Starr. Montreal was selected as the place of meeting in 1902, and a suggestion was left with the members of the association that they meet in British Columbia the following year. The following officers were elected for the ensuing year: *President*, F. J. Shepherd of Montreal; *Vice-Presidents*, S. R. Jenkins of Charlottetown, T. F. Macdonald of Hopewell, W. Christie of St. John, J. Alex. Hutchinson of Montreal, Bruce L. Riordan of Toronto, A. J. Macdonnell of Winnipeg, H. G. McKid of Calgary, and J. M. Lefevre of Vancouver; *General Secretary*, George Elliott, 120 John street, Toronto; *Treasurer*, H. B. Small of Ottawa; *Executive Council*, Jas. Stewart, T. G. Finley, and J. M. Elder.

New Instruments.

A NEW ELECTRODE.

By WILLIAM H. ROGERS, M.D.,
NEW YORK.

HAVING for several years felt the necessity for stronger galvanic currents in the treatment of uterine fibroids and all chronic inflammations of the female pelvic organs, I have been searching for and devising electrodes and methods by which I could get a current of one hundred to one hundred and twenty-five milliampères without causing an ulceration in the vagina or on the cervix.

I have never been able to use a galvanic current of over fifty milliampères for any length of time without causing these erosions and being forced to

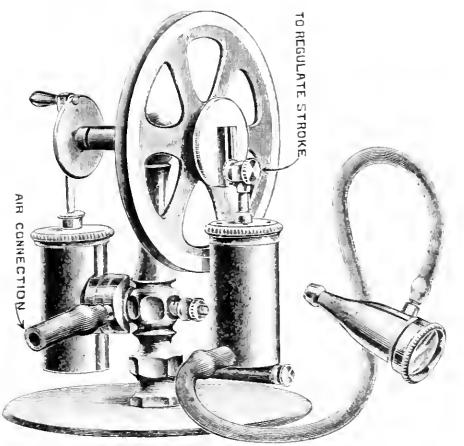
interrupt my treatment. I have now, however, an electrode with which I can use one hundred to one hundred and twenty-five milliampères with almost perfect comfort to the patient, and without the danger of causing a sore. The electrode is simple and easily sterilized.

The accompanying illustration represents a hard rubber speculum which can be bought in nests of five sizes, closed with a rubber stopper with three holes through it, one for the electrode, one to allow the escape of gas, and one to facilitate the emptying of the speculum, which is filled with a weak solution of bicarbonate of sodium. It is necessary to use a good rheostat, so that one can put on and take off the current without shocking the patient. I believe that the application of a current of one hundred to one hundred and twenty-five milliampères is as effective as puncture in the reduction of fibroids. I hope those who may use this electrode will find it as effective as I have.

225 WEST TWENTY-SECOND STREET.

A NEW EAR MASSEUR.

MANY attempts have been made to construct an appliance for the massage of the membrana tympani, but most of the appliances have contained more or less serious defects in the mechanical construction, which led to uncertain results. The accompanying illustration shows a new ear masseur made by George P. Pilling & Son which, it is claimed,



does the work properly and safely. It is on the double cylinder principle, which insures a smooth running apparatus. The length of stroke can be regulated by the adjustable piston, and to the apparatus is attached an otoscope with magnifying lens to enable the operator to watch the operation. The apparatus is operated by compressed air from the usual compressed air tank commonly found in physicians' offices.

The Nose and Throat in Their Relation to Diseases of the Chest.—William Scheppegrell states that the normal nasal passages form a distinct barrier to the entrance of pathogenic germs, and emphasizes the fact that abnormalities of nasal respiration may develop irritation of the lower respiratory organs, hence this possibility should not be overlooked in treating diseases of the chest. No case of bronchitis or asthma should be deemed incurable until the upper air passages have been examined and existing abnormalities corrected. He considers that examination of the upper air passages should always be made without delay in treatment of diseases of the chest, and believes that correction of existing deformities there will often give relief even when secondary changes have occurred in the deep respiratory structures.—*New Orleans Medical and Surgical Journal.*

Surgical Suggestions.

Various Suggestions.—In delirium tremens, when the action of sedative drugs is apparently insufficient to obtain rest and sleep, a blister or a mustard plaster applied to the back of the neck often has an excellent effect.

Little children should never be operated on during very hot weather if the surgeon can choose his own time. They are very apt at this time, however carefully they are fed, to develop a severe form of intractable diarrhœa.

Atheroma of arteries does not contraindicate amputation so much on account of the danger of hemorrhage as because, in these cases, the flaps slough easily, owing to lowered vitality. Hence it is necessary to select the operation that will give the best blood supply.

Discard carbolic acid entirely in the treatment of wounds in children. Not only do they develop gangrene very readily from its continuous effect in wet dressings, but fatal cases of poisoning have been known to occur from the application of so weak a solution as 1–40.

In any operations in which the muscles and fasciæ are divided, it is well to remember that these structures are apt to become further separated on account of the handling of the parts during the operation. Hence it is well, when suturing these structures, to pull the skin at the angles of the incision in order to make sure that no divided tissues extend beyond the limits of the original incision.—*International Journal of Surgery.*

Furuncles and Felons cured without pain.—Inject with a very fine needle a few drops of cocaine solution. Introduce a larger needle and inject several drops of a ninety-five per cent. carbolic-acid solution.—*Sanative Medicine.*

Hemorrhoids.—Introducing enough carbolic acid into the mass to produce a slough has no advantage over the ligature or clamp and cautery and may cause disastrous consequences. Injecting a sufficient quantity to obstruct circulation and cause resolution is a method applicable to a large number of cases. The sphincter should always be relaxed to avoid strangulation, there should be no ulceration, and simple internal hemorrhoids alone should be operated on this way. After the rectum is flushed and the parts are scrubbed, the needle is inserted at the juncture of the tumor with the mucous membrane and carried across its base until the mucous membrane on the opposite side is reached. Inject little by little as the needle is slowly withdrawn, and carried again first to one point then to another. A small barrel syringe is best, and from three to ten drops are sufficient. The needle should be left in position one or two minutes. Inject one hemorrhoid at a time, with a three days' interval between the injections. The bowels should be confined for 48 hours. Shuford's modified solution is recommended:

R	Acidi carbolici	ʒiss
	Sodii biboratis	ʒi
	Acidi salicylici	℥ss
	Glycerini	ʒi

This should be made a clear solution to avoid obstructing the syringe and producing irritation.—James P. Tuttle, *International Journal of Surgery.*

Obscure Fracture near the deltoid in a very obese subject.—A piece of poroplastic material, oblong in shape, and wide enough to take a good hold of the trunk, was folded lengthwise so that the arch of the fold fitted into the axilla and the outer limb acted as a support to the arm, reaching as far as the bend of the elbow. At the axillary bend lateral incisions were so fashioned that the edges of the poroplastic material could be bent outward, encircling the arm, forming a sort of trough splint; the ears formed by the lateral incisions passing up in front and behind the shoulder, acted as a shoulder cap—the thoracic piece was fixed to the trunk by broad strips of adhesive plaster, and the parts enclosing the arm were secured also by pieces of strapping.—R. B. Nevitt, *Dominion Medical Monthly.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 31, 1901.

	Cases.	Deaths.
Measles	47	9
Diphtheria and croup	108	6
Scarlet fever	66	6
Smallpox	19	4
Chickenpox	..	..
Tuberculosis	194	130
Typhoid fever	114	25
Cerebro-spinal meningitis	..	3

The Action of Ovarian Juice on Blood Crasis.—Antonio Rondino states that the injection of ovarian extract in moderate doses is well tolerated by animals. Pregnant animals are the most sensitive to its action, so that the dose must be reduced one-half. The effect upon the blood is to increase the number of the red blood cells, and of the leucocytes and hæmoglobin. The system, however, does not become tolerant of the juice, for the injection of 5 c.c. in a rabbit, or 3 c.c. in a pregnant rabbit, will cause death within a few hours. A little while before death, there is marked diminution of the red blood corpuscles and other constituents of the blood. —*Giornale della Associazione Napoletana.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending September 7, 1901:

		Cases.	Deaths.
Smallpox—United States.			
California, Los Angeles	Aug. 17-24	1	
San Francisco	Aug. 18-24	2	
Kansas, Wichita	Aug. 24-31	1	
Louisiana, New Orleans	Aug. 24-31	1	
Massachusetts, Boston	Aug. 24-31	6	
Minnesota, Minneapolis	Aug. 17-24	5	
Nebraska, Omaha	Aug. 24-31	2	
South Omaha	Aug. 23-30	2	
New Jersey, Newark	Aug. 24-31	5	2
New York, New York	Aug. 17-31	37	13
Pennsylvania, Philadelphia	Aug. 24-31	31	2
Utah, Salt Lake City	Aug. 18-24	2	
West Virginia, Wheeling	Aug. 18-31	1	
Smallpox—Foreign.			
Austria, Prague	Aug. 10-17	1	
Belgium, Antwerp	Aug. 3-10	1	
Brazil, Rio de Janeiro	July 28-Aug. 4		42
Colombia, Panama	Aug. 19-26	10	
France, Paris	Aug. 3-17		19
Great Britain, Dundee	Aug. 10-24	4	
London	Aug. 10-17	13	2
India, Bombay	July 30-Aug. 6		2
Calcutta	July 27-Aug. 3		5
Madras	July 27-Aug. 2		9
Italy, Messina	Aug. 10-17	7	1
Naples	Aug. 10-17	119	17
Mexico, City of Mexico	Aug. 18-25	2	
Russia, Moscow	July 27-Aug. 10	4	3
Odessa	Aug. 3-17	2	1
Warsaw	July 27-Aug. 10		5
Yellow Fever.			
Brazil, Rio de Janeiro	July 14-23		7
Colombia, Bocas del Toro	Aug. 21	1	
Costa Rica, Port Limon	Aug. 14-18	8	4
Cuba, Cumanayagua	Aug. 17-24	1	
Matanzas	Aug. 31	2	
Cholera.			
India, Bombay	July 30-Aug. 6		8
Calcutta	July 27-Aug. 3		17
Madras	July 26-Aug. 2		26
Japan, Yokohama	July 20-Aug. 3	2	
Straits Settlements, Singapore	July 6-13		1
Plague.			
Brazil, Rio de Janeiro	July 14-28		4

PATHOLOGICAL PHYSIOLOGY OF THE ANIMAL HEAT ECONOMY AND ITS RELATION TO THE MODERN THEORIES OF FEVER.

BY ISAAC LEVIN, M.D.,
NEW YORK.

AN animal body is normally warmer than the medium which surrounds it. This is true not only of the warm-blooded animals, but of the cold-blooded as well, whose temperature is higher than that of the medium, though only a small fraction of a degree. The only difference that exists between them is that the latter change their temperature with that of the medium, while the warm-blooded animals keep their temperature constant, with very slight periodical variations, whatever may be the change of the temperature of the medium. The first are called, therefore, poikilothermic (animals of varied temperature), and the latter homoiothermic (animals of constant temperature).

For a warm-blooded animal, as well as a human being, this constancy of temperature is an absolute necessity for the continuation of life. As certain bacteria can grow only at a certain temperature, so is a human being able to live only when his temperature has not gone below 34° C., or above 42° C. Further, even in these narrow limits, the organism is in an entirely normal condition only when its temperature is 37° C., or very near it, otherwise it must be considered pathological.

The pathological physiology of animal heat, in its every phase, is so closely connected with the normal that the study of the first cannot be begun without at least a superficial perusal of the normal physiology of animal heat.

Physics teaches us that heat is one of the forms of energy innate in every substance or body. A certain state of such a body with respect to heat, in comparison with other bodies or substances surrounding it, is what we call temperature. A certain temperature is consequently only a comparative quantity, and does not show at all the real amount of heat in a body. On the contrary, physics has shown that in order to raise the temperature of different bodies one degree we need different amounts of heat. The real amount of heat is measured by another unit, the calorie, *i.e.* the amount of heat necessary to raise one kilogram of ice-cold water 1° C. (small calorie means the amount necessary for one gram of water).

As has been mentioned before, every organism needs a certain amount of heat to exist. But a warm-blooded animal has always, under ordinary circumstances, more heat than the medium it is in; consequently, by the law of physics, it must constantly distribute part of its heat to that medium. It is self-evident that the organism cannot retain its constant amount of heat without just as constantly acquiring or producing new amounts of heat. What are, then, the sources of animal heat?

The food introduced into an organism undergoes different analytical changes until its final oxidation into CO_2, H_2O, and urea. During these processes a certain amount of energy is freed, of which a smaller part manifests itself in different work of the organism, and a great deal larger part in heat. This amount of energy will be the same whether some organic matter will be immediately oxidized into CO_2, H_2O, and urea, or it will previously undergo some intermediate stages before its final oxidation.

Food, or, rather, the process of its metabolism, is practically the only source of animal heat in the normal state of the organism. The fact that a starving organism is able to preserve pretty nearly its normal temperature for a certain time does not refute this theory. It only shows that a starving organism oxidizes some constituents of its own body, thereby freeing at least some amount of energy. This can be seen from the fact that a starving organism constantly loses its weight.

This influence of food on the production of heat in the organism must not be construed in such a manner that the amount of heat simply depends on the amount of food taken. Mechanics proves that in order to produce a certain amount of work, every machine needs a far greater amount of potential energy, the rest of which manifests itself in heat. The animal organism is the most economic machine in this respect, and still it is able to use only about a fifth of its energy for actual work (Rubner). There is some work that an organism is always bound to perform, for instance, the work of the heart, glandular system, and so on, and all of this increases the amount of heat production. Far greater yet is the influence of the work of the muscular system on the production of heat (Roehring and Zuntz). It is a well-known fact that an hour or so of a good run may raise the temperature of the body as high as two degrees. We can see, then, that an organism at work produces more heat than one resting. They may both consume the same amount of food, but the latter organism will oxidize and realize the energy of only a part of the food, while the rest of the food will undergo some preliminary changes (into fat, for instance), and with a part of its energy will be left over, so to say, in storage. The working organism, on the other hand, will fully oxidize and use up all the energy of the food ingested.

It easily follows from this that the measuring of the heat produced in an organism is closely connected with the knowledge of the amount of food oxidized in the organism. This measurement can be accomplished in one of the following ways:

1. Determine during a rather long period of time the amount of food necessary to keep a certain organism perfectly balanced in regard to the state of its heat and its weight, and then measure the potential energy of that food.

2. Determine during twenty-four hours the amount of food introduced into an organism and the amount of the products of metabolism eliminated; measure the respective energy, and the difference between the two last determinations will show the amount of heat produced in the twenty-four hours.

3. Determine the respiratory coefficient or the relation between the formed CO_2 and consumed O_2.

This is the best method of determining the heat production.

Lavoisier, and later Pflueger and Voit, have shown that an animal put in an atmosphere of pure oxygen consumes not more of it than in an ordinary atmosphere. The amount of oxygen consumed depends only upon the amount of the metabolism in the body. Consequently, by the amount of the oxygen consumed we can judge the amount of food oxidized, and thereby the amount of heat produced in the body. But different foods require different amounts of oxygen in order to be oxidized to their last products of decomposition: 100 gm. of O_2, for instance, can oxidize 35 gm. of fat, 84.4 gm. of carbohydrates, 74.4 gm. of albumen. We must, therefore, determine also the amount of eliminated CO_2, as the relation between these two agents $\left\{\frac{\text{(eliminated } CO_2)}{\text{(consumed } O_2)}\right\}$ is fairly constant for every kind of food; we shall then be able to determine what kind of food was oxidized, and what quantity of it. Having determined this, we can easily infer the amount of potential energy, and consequently of heat, produced within the body. It has been calculated that there is constantly produced within our body an amount of heat sufficient to raise our temperature two degrees an hour, or forty-eight in twenty-four hours. It is obvious that this amount of heat would be sufficient to burn the organism if it were not constantly distributed into the surrounding medium.

Like every other physical body of a temperature higher than that of the surrounding medium, an animal organism loses its heat through radiation and conduction. This loss takes place at the surface of the body only, and depends upon the relative size of the surface and the weight of the body; smaller animals, therefore, lose more heat for every kilo of their weight than do larger animals. The difference between this distribution of heat through radiation and conduction in an inanimate body and that in a living organism consists in the ability of the latter to change the temperature of its surface, and consequently the amount of heat lost, by means which will be shown later.

It will be appropriate to mention here that in a human body the clothing has a great influence upon this loss of heat. The heat from the skin is transferred to the so-called inner atmosphere, or to the air existing between the skin and the clothing. The last being a worse conductor of heat than the skin, there is always a part of the distributed heat left over in the inner atmosphere, the temperature of which is consequently higher and more even than that of the atmosphere surrounding it. This fact is of great importance, as we would be otherwise unable to withstand the great climatic changes. All other animals are protected by felt, fur, or feathers, that are all worse conductors of heat than human skin.

Besides radiation and conduction, there are some other means by which animal heat is lost. The most important of them is the evaporation of the water secreted through the perspiration of the skin and with the expired air. Such evaporation is always accompanied by an expenditure of a considerable amount of heat. And lastly, some part of animal heat is consumed in warming the air and food we are taking in.

The full amount of heat lost by an animal during a certain period can be measured by an apparatus called a calorimeter. There are two kinds of such apparatus in existence, the water-calorimeter and the air-calorimeter. The idea of the water-calorimeter is as follows: An animal is placed in a metal box with double walls. The space between the two walls is filled with a measured amount of water. The heat lost by the animal warms the water. Knowing the difference in the temperature of the water before and after placing the animal in the box, and the amount of water, we can measure the amount of calories consumed by the water, and consequently lost by the animal. The outer wall of the apparatus is covered by a nonconductor of heat, in order that the heat of the water may not be easily lost in the atmosphere.

Recent researches of D'Arsonval, Rosenthal, and Rubner show that the air-calorimeter is a great deal more sensitive, and gives better results. The construction of this calorimeter is based upon the physical fact that heating a gas always increases its volume, or, if that gas be inclosed in a certain space, increases its pressure. The air-calorimeter is also a box with double walls, but in the space between the two walls there is air connected with a manometer. When an animal is placed in the box it raises the temperature of the air between the walls to a certain degree, raising thereby at the same time its pressure to a certain amount, and this is shown on the manometer. The manometer is measured previously by placing in the box a hot object, of which the loss of heat was determined beforehand.

We have previously mentioned that the difference between the poikilothermic and the homoiothermic animals consists in the ability of the latter to keep a nearly constant temperature, notwithstanding the different conditions the organism may be in with regard to the amount of heat produced and lost. There must be, no doubt, a very sensitive mechanism which can effect such constancy of the temperature of a homoiothermic animal. To get a clear understanding of this regulative mechanism, we must know, on the one hand, its nature, and, on the other, the ways and means of its action. The latter part of the question is a great deal easier to comprehend, and has consequently been worked up better; we will therefore begin with it.

Let us consider a case in which, for some outside reason, say the low temperature of the surrounding atmosphere, a greater amount of heat has to be lost from the surface of the body. The regulative mechanism works against it in the following manner: Through the circulation of the blood, heat is constantly transferred from the internal parts of the body to its surface. Under the influence of cold, the minute blood-vessels of the skin contract, the amount of blood passing in a certain time through the skin, and thereby the amount of heat, is lessened. Consequently, the temperature of the skin, which is always lower than the inner temperature of the body, becomes lower still. The loss of heat through conduction depends upon the difference between the temperature of the atmosphere and the surface of the body; it diminishes, consequently, under the influence of cold. The perspiration of the skin and the resultant evaporation of water cease entirely. All this tends to decrease the loss of heat. Besides this, the production of heat increases under the influence of cold. An animal under the influence of a low temperature digests a greater amount of food in general, and more fat in particular, the latter producing more heat by its oxidation than any other food; there are more voluntary muscular contractions, as well as involuntary ones in the form of chills, which are fibrillary contractions of the whole muscular system. Pflueger and Zuntz have endeavored to prove that there is also, under the influence of cold, an increase of metabolism in the muscles independent of their physical work; in other words, that cold increases the chemical tonus of the muscular system. But this has been since dis-

puted, as they could not exclude in their experiments the smallest fibrillary muscular contractions.

Exactly the contrary takes place if the temperature of the atmosphere increases. The blood-vessels of the skin dilate, thereby bringing a greater amount of heat from the internal organs to the skin, which increases the amount of heat the skin loses through conduction. The secretion of water by the skin and lungs increases; consequently, a greater amount of heat is lost by evaporation. The animal digests less food, lies still, without any muscular movements, which all tends to decrease the heat production.

All these physiological actions of the circulatory, muscular, and glandular systems before mentioned, by the aid of which the heat of the organism is regulated, are themselves under the influence of the nervous system. The regulative mechanism of heat itself is so sensitive that there can be no doubt as to its nervous nature.

But is there a part of the nervous system that has for its office the regulation of heat, and if so, where does it lie? This question is far from being answered conclusively as yet. The most striking proof that the constancy of temperature of the homoiothermic animals is produced by the influence of the nervous system is given by the experiments of Zuntz and Pfluege, showing that a curarized animal, or an animal whose spinal cord has been severed between its cervical and dorsal parts, becomes practically poikilothermic, and changes its temperature with that of the atmosphere. This explains the seeming disagreement between the earlier works of Fischer, who found a decrease of temperature after severing the spinal cord, and those of Tscheschichin and Nauny and Quinke, who found even a slight increase if they covered the animal or put it into a warm medium. All these works certainly do not show any specific influence of the nervous system on the production of animal heat. The severing of the spinal cord produces a dilatation of the blood-vessels and a paralysis of the muscular system, thereby increasing the loss of heat and doing away with the most important source of heat production.

We find far greater difficulty when we search for the influence of the brain upon animal heat.

Tscheschichin and Wood found that an injury of the brain between the pons and medulla raises the temperature of the animal, and they promulgated the theory that there must be near the pons a nerve center, whose function is to inhibit or repress the production of animal heat, the injury of which increases this production. But the constancy of this phenomenon was refuted by Rosenthal and others. Landois and Eulenburg, Hitzig and Wood have also shown that injury of the motor regions of the brain raises the temperature of the body; but this fact seems to throw little light upon the rôle the nervous system plays in the regulation of the animal heat, for such an injury produces in the animal epileptic convulsions, which are alone sufficient to raise its temperature. A great deal more promising seem to be the investigations of the deeper parts of the brain. Aaronson and Sachs, Richet and Ott have almost simultaneously shown that a lesion of the corpus striatum near the nodus cursorius, and of the adjacent places of the brain, raises the temperature of the body three to four degrees. This increase of the temperature may last for three or four days, and does not depend upon the temperature of the medium surrounding the animal. It is sufficient to prick this place in the brain with a needle to raise the temperature, and the experiment can be repeated on the same animal with the same result. The deeper a needle goes in, the higher will be the temperature.

White has found later some other places in the brain injury of which produces the same effect. In other places of the brain, again, the effects of such an injury would be to lower the temperature (Ott). We can now see that, though the last-mentioned works do not seem to leave any doubt that the brain has a direct influence on the regulation of the animal heat, we are still unable to determine whether there is a special center for it, or whether different parts of the brain, through their influence upon the circulatory, muscular, or other systems, do the work of regulating the animal heat. Just as little is known through what channels, through what kind of peripheral nerves, this regulation is produced. Cl. Bernard's "nerfs frigorifiques et calorifiques" are not proven to be special nerve fibers transmitting heat reflexes, but are most probably vasomotor nerves.

The constancy of temperature, as we have mentioned already, is an absolute necessity for normal animal life. Temperatures above or below the normal show that the organism is in a pathological state. The temperature depends upon the relation between the heat produced and lost, and this, in its turn, upon the relation between the animal heat and amount of heat in the surrounding atmosphere. Consequently, the decrease and rise of temperature may depend upon the changes in the temperature of the atmosphere or in the amount of internal animal heat

The capacity of an organism to regulate its state of heat against the influence of low atmospheric temperature is limited; if this temperature is too low or if its influence continues too long, the organism must undergo certain pathological changes. The action of the heart of such an animal becomes very slow, the arterial pressure low, the breathing frequent and superficial; the secretion of urine decreases, the reflexes cease, there appears a general paralytic state of all the organs, and at last the animal dies in convulsions. These facts are proven to be true clinically, as well as experimentally, in the case of animals put into ice-boxes, or into whose veins a cold physiological salt solution is injected (Horwath, Walter, and Knoll). The action of a low atmospheric temperature on the organism, a so-called "cold," was considered of the greatest importance in pathology before the science of bacteriology was developed. The origin of almost all acute infectious diseases was ascribed to its influence. But with the advent of bacteriology there seemed to be a tendency to deny the influence of a "cold" entirely, though this certainly controverted long clinical experience. Such an influence upon the organism of a rapid decrease of the temperature of the atmosphere certainly exists, though this decrease is not always great enough to injure the organism directly. There are a great many theories in existence explaining the influence of a "cold" on the organism, as, for instance, that the decrease of the atmospheric temperature injures the action of the skin, that it irritates the sensitive nerves, alters the trophic nerves, etc., but none of them is capable of explaining fully the phenomenon. Lately, Lipari, Filehne, and Lode have proven experimentally that animals previously cooled off yield to bacterial infection easier than normal animals. Thereby the existence of a "cold" is proven not only clinically, but experimentally as well, though we still do not know its mode of action Possibly the influence of a rapid decrease of atmospheric temperature consists in decreasing the force of resistance of the animal cells against the bacteria and their toxins.

There are, also, undoubtedly pathological conditions, when the temperature is below the normal, consisting in some lesion in the regulative mechanism. At least, the most plausible explanation of the death

of animals after extensive burning, or experimental varnishing of the skin, is the cooling off of the organism through an abnormal loss of heat. Falk has proven experimentally that the loss of heat after the burning of the skin is increased, and Valentine and Winternitz have also proven that the death of an animal after varnishing the skin can be delayed, and even stopped, if it is put into a warm medium.

But temperatures above normal are of much more importance in pathology. They can also be produced by an outside cause, *i.e.* the high temperature of the surrounding atmosphere.

Rosenthal has shown experimentally that, if we put an animal in a box and raise its temperature above 32° C., the temperature of the animal increases to about 41° or 42° C. The animal lies still, the peripheral vessels are dilated, and the pulse and breathing are accelerated, though the last is more superficial. If the temperature of the box is raised to 40°–42°, then the temperature of the animal increases to 42°–45°, and it dies under symptoms of general paralysis, exactly with the same symptoms we meet in cases of insolation or sunstroke, where an organism is just as abruptly put under the influence of an atmosphere with an unusually high temperature, as in the experiment.

Besides the symptoms of the high animal temperature produced by a high temperature of the atmosphere, which we mentioned already, it will be interesting to state that Simanowsky has shown experimentally, and P. A. Levene on sunstroke patients, that, notwithstanding the high animal temperature, the N elimination, and consequently the metabolism, is not increased. Richter, however, has refuted Simanowsky's results.

The cause of death from overheating cannot be clearly defined as yet. Cl. Bernard believed that coagulation of muscular albumin (myosin) was the direct cause of death, but this theory was refuted by Heubel, who proved that a heart that has stopped beating under the influence of very high temperature (45.5°), if cooled off may begin to beat anew. More probable seem to be the opinions of Ide, who says that through the influence of overheating the work of the heart is arrested by the action of some toxic substances accumulated in its muscular tissue, without its morphological structure being injured, and of P. A. Levene, who thinks that the symptoms and death from sunstroke are due to autointoxication of the organism.

FEVER.

We turn now to the study of the pathological increase of the animal temperature, due to causes emanating from the organism itself. Hippocrates and Galen recognized such a "calor praeter naturam" as a disease, and called it πυρετός, febris, fever. Formerly, fever always meant a certain disease manifested by an elevation of the temperature, changes in the action of the heart and lungs, altered metabolism, and morphological changes in the parenchymatous organs. But all these symptoms accompany so many entirely different pathological processes that there can be no doubt in anybody's mind that a great variety of processes, often having nothing in common among them, are called by the same name—fever. What else but the name is there in common between hysterical fever and the fever in malaria, for instance? A great many pathologists have endeavored to correct the misuse of the word fever.

It is easily comprehensible that fever does not mean a certain disease, but a certain pathological condition of the system, that may be the result of or simply accompany a great many different diseases. Of all previously mentioned manifestations of fever, the elevation of temperature is the most important, for where there is no high temperature there is no fever. Fever, consequently, is a diseased state of the heat economy of the organism, in which the temperature of the body is raised above the normal.

The question arises, now, whether every elevation of temperature can be called fever. It seems somewhat unwarrantable to assume that a person who has been running for some time, and has thereby raised his temperature one or two degrees, is in the same pathological condition as one having malarial fever. Different measures have been, therefore, taken to differentiate one kind of elevation of temperature from another. The best of these would seem to be the one expressed by Liebermeister and, later, developed by Filehne, Richter, and Stern. They hold that there exist simple elevations of temperature, and febrile ones. A febrile elevation of temperature, or fever, they consider to be present only in cases in which the temperature is not only raised but leveled on this raised point. What they mean by it is as follows: If we forcibly reduce the temperature of a person with a simple elevation of temperature by some agent, we can reduce it to the norm, and it will remain there, even after the agent has ceased to act; while if we do the same with an individual having fever, the temperature will not sink entirely to the norm, and will rise again to the former height as soon as the agent has ceased to work. In other words, the organism, in its febrile state, just as strenuously opposes the reduction of its high temperature as the normal organism does the reduction of its normal temperature, while an organism in a state of simple elevation of its temperature begins the work of contra-regulation only after the temperature has been reduced to the norm.

Liebermeister first based the construction of this theory upon the fact noticed by him that a fever patient in a cold bath preserves as far as possible his high temperature, and very soon after the bath the temperature attains the point it had before the bath. Loewy and Richter have tried to prove that there is an actual qualitative difference between these two kinds of elevation of temperature by the fact that, while they have often found the alkalinity of blood increased in febrile elevations of temperature, they have never found it in the simple ones.

This theory is ingenious, but it does not seem to introduce any qualitative difference between the two kinds of elevation of temperature, but simply a quantitative one.

Should we agree that fever is, in the first place, a pathological state of the heat economy, and that all the other manifestations in fever are the result of the high temperature or else simply accompany it, and that there is no fever without a high temperature, then we must admit that fever is produced by some cause affecting the different heat-regulating mechanisms. Now if, in one case, such a cause gives a certain shock to the regulative mechanism, and then ceases its action, while in another case the cause acts continually, it is self-evident that in the first case the temperature will be easily reduced to the norm, while in the other it must remain at its high level, because the regulative mechanism receives the second shock before the antipyretic has had time to act. The difference, consequently, does not lie in the nature of the different fevers, but in that of the causes producing them. The difference in the alkalinity of the blood is, in the first place, not definitely proven yet, and it is not proven whether

it has anything to do with the febrile elevation of temperature in any case.

But as long as we do not find any qualitative difference in the various elevations of temperature, as to their nature or as to the influence they produce upon the organism, we must coincide with the opinion of Unverricht, that every elevation of temperature must be called fever; but we would add, every elevation of temperature due to causes emanating from the organism itself. In this way we exclude all elevation of temperature due to overheating, and, except the cases of slight elevation of temperature due to muscular work, the name of fever will apply to the same thing in general pathology as in clinical medicine.

None the less, fever appears in different forms, and has to be subdivided. Falkmann's subdivision of fever into simple and complicated seems to suit the purpose best. The simple fever of Falkmann corresponds to the simple elevation of temperature of Liebermeister (not perfectly, though), and includes fever in the course of some nervous diseases, in simple fractures of bones, in anæmia, and so forth; while the complicated fever of Falkmann, or the febrile elevation of temperature of Liebermeister, includes, in the first place, fever in infectious diseases.

As was mentioned above, the difference between the fevers consists in the difference between the causes producing them. The study of these causes is of the greatest importance for the understanding of the whole process, but before we begin it we must try to show in what way these fever-producing or so-called pyrogenic agents must act in order to cause fever.

An elevation of the temperature can be caused by increasing the production of heat, by decreasing the loss of it, or by different combinations of both. Lavoisier, who has shown experimentally that respiration represents the act of combustion of organic substances of the organism, has expressed the opinion that fever is produced by an increased combustion, or, what is the same thing, by an increased formation of heat. The experimental development of this theory is due to the works of Liebermeister, Pfluege, and Leyden, and their followers. Liebermeister has shown that a patient with a temperature of 106° F., put in a bath with a temperature of 86° F., loses 198 calories of heat (calculated by the change of the temperature of the water), while his temperature decreases only about 2° F., which indicates a loss of about 38 calories of heat (taking the heat coefficient of the body at 0.83).

On the basis of this fact, Liebermeister comes to the conclusion that there exists in fever a constant overproduction of heat, which would account for a part of the heat lost in the bath. To the same conclusion also came Pfluege and Leyden through finding the respiratory coefficient increased in experimental fever. Now, this increase in the production of heat is certainly not sufficient to explain entirely the phenomena of fever. In the experiments of Liebermeister, the increase of heat production might have been due not to the fever itself, but to the influence of the cold bath. As to the increase of the respiratory coefficient, Krauss has proven that it is too small to explain the temperature in fever. Traube was the first to show the weak points of this theory and the great importance the change of the loss of heat has in fever. He drew his conclusions from cases in which fever begins with an acute chill. The following is the explanation he gives of the origin of fever: Under the influence of some pyrogenic cause, the small arteries of the skin contract, thereby lessening the amount of heat coming to the surface from the internal organs, as well as the amount of heat dissipated. With him, consequently, fever is simply a heat stasis in the internal organs of the body produced by a decreased loss of heat. In fever, not accompanied by a chill, he accepts the same mechanism, only working not so abruptly. But the increase of the loss of heat alone is just as little able to explain the febrile elevation of temperature as is the increased production of heat alone. This fact is admitted by modern experimenters, no matter whether they adhere to Liebermeister's or to Traube's theory. So, for instance, Senator and Rosenthal have admitted a certain influence of the increased heat production in fever, though the decreased loss of heat is with them the most important factor in producing it. On the other hand, Leyden, an adherent to Liebermeister's theory, admits a decreased loss of heat, though he ascribes it not so much to the contraction of the cutaneous arterial system, as to the retention of water in the organism, when there is no sweating or any other loss of water in the febrile state of the organism. From a study of the above-mentioned, as well as a great many other works on the subject, the following conclusions can be drawn: In the first stage of fever (stadium incrementi), the most important factor really consists in the decreased loss of heat through the contraction of cutaneous vessels. At the height of fever (fastigium), the loss of heat is even increased sometimes, but the production of heat is always so much increased that it covers the increased loss, while in stadio decrementi the loss of heat is higher than the production, the retained water is freed, and as a consequence of all this the temperature falls.

We see, now, that the mechanism of fever is very complicated; the causes producing it cannot act simply by increasing the production of heat or decreasing its loss. We have seen already that in a normal organism an increased production of heat by whatever cause is immediately contra-regulated by as great increase in the loss of heat, and vice versa, while in fever very often just the contrary takes place. All this can only be explained, if we admit with Tscheschichin, Wood, Aaronson and Sachs, and others, that the fever-producing agent affects primarily the regulative mechanism in the central nervous system, changing its action in such a manner as to produce an increase in the temperature.

We have seen already that the name fever does not imply a uniform pathological process, and that the agents producing fever must also be of differing natures. In studying the agents producing different kinds of fever, we must always keep in mind Falkmann's classification into septic, or infectious, and aseptic fevers. In infectious fevers the causes of the elevation of the temperature, as well as of the diseases themselves, are closely connected with the microorganisms producing them. The action of these microorganisms does not consist in any mechanical influence produced on the organism by their presence, but in the toxic action of the products of their metabolism. This can be proven by the fact that a sterile culture of fever-producing microorganisms can also produce fever. Further, Bergmann and Brieger extracted from such cultures chemical substances that were able to produce the same pyrogenic action as the cultures themselves. (Ughetti, on the basis of his observation of malarial and recurrent fevers, comes to the conclusion that the action of microorganisms consists in the mechanical breaking up of the red blood corpuscles,

and the resultant detritus in its turn mechanically produces fever, but he does not give any experimental proof of his theory, neither is it supported by anyone else.)

It must be borne in mind that a substance producing fever in a certain infectious disease, and the substance producing the pathological process itself, are not the same, as can be seen from the fact that some microorganisms are not pathogenic at all, in the usual sense of the word, and they still produce fever. Neither are pyrogenic substances in the different microorganisms of the same nature. Krehl has shown, for instance, that the action of the pyrogenic substances in some microbes decreases under the influence of heat, while in others it does not. Centanni's opinion that fever is always produced by the same substance, "pyrotoxin," has not been confirmed. Buchner and Krehl hold that a pyrogenic substance is always some kind of an albuminous substance, a toxalbumose, constituting a part of the body of the microorganism; therefore a dead culture is also able to produce fever, as, for instance, in the case of Koch's tuberculin. We see, consequently, that infectious fever is a certain kind of intoxication affecting the heat-regulating mechanism of the nervous system.

But it seems that even in a great many of the so-called aseptic fevers (in subcutaneous traumas, blood diseases, etc.) the same explanation is the most plausible. At least, it has been shown that fever can be produced by a subcutaneous or intravenous injection of aseptic organoextracts (Paulsen). Krehl tried, with the same object in view, a great variety of albuminous substances, but he could not come to any conclusive or uniform results. The most satisfactory results seems to give albumoses. Mathes has proven that not only are these albumoses able to produce fever, but that they are all able to produce on a tuberculous organism the same reaction as tuberculin does. He has also very often found albumoses in the urine of febrile patients. If, now, we take into consideration that albumoses are formed whenever necrotic tissue is absorbed, the relation between fever and albumoses seems to be close indeed. Still, even this fact does not give us any hope of finding a uniform cause for fever. Krehl and Mathes state that a chemically pure albumose, but derived from a bacterial culture, has a great deal stronger pyrogenic action than an albumose derived from plain albumin. Besides this, fever is unquestionably sometimes produced by a simple reflex action through the vasomotor, sensitive, or some other peripheral nerves, on the heat centers, or by primary lesions of these centers. At least, no other explanation can be given for the fever arising immediately after catheterization, in traumas, or some diseases of the brain, or for the experimental fever produced by Aaronson and Sachs and others, by simply injuring certain parts of the brain.

The conclusions derived, then, from the study of the pathology of the heat economy are as follows: Heat economy seems to resemble general metabolism inasmuch as it is a result of the joint work of many organs of the body; and fever, the most important pathological state of heat, is in most instances a special kind of intoxication by some substances not as yet well defined. Further work will have to show us the precise nature of these substances, and also decide the question whether there is some central apparatus conducting all the complicated works of the heat economy, and what the nature and office of such an apparatus are, if it does exist.

We have seen already that fever is usually accompanied by changes in the functions of nearly every organ in the body, among which the most important are the changes in general metabolism, and in the action of the circulatory and respiratory organs, and the morphological changes in the parenchymatous organs. We have shown that none of these changes can be the sole cause of the febrile elevation of temperature. On the other hand, we have no proof to show that the above-mentioned changes are a result of the febrile elevation of temperature.

The change in metabolism, for instance, consists in increase of the decomposition of the animal tissues, and most particularly of the albuminous parts of them; but the same increase in decomposition we find continues in febrile diseases even after we have reduced the temperature by antipyretics. Sometimes such an increase begins before the rise of the temperature has taken place; besides this same increase of tissue decomposition, we find, in cancerous cachexias and anæmias, diseases that are not accompanied by fever. The same can be said about the increased elimination of N-containing substances and salts in the urine, and about the loss of weight in fever, as this all is simply a result of the increase in tissue decomposition.

A great deal closer are the connections between the febrile elevation of temperature and the accelerated respiration and action of the heart, as both can be produced by the simple elevation of the temperature. It has been proven, even, that under the influence of heat the contractions of a frog's heart severed from its body become more frequent. Still, these changes continue, even when the temperature is artificially lowered. The most probable explanation, therefore, of all the above-mentioned changes accompanying fever is that they are not dependent in any way upon the elevation of the temperature, and the connection between them exists only inasmuch as they are most probably produced by the same agent. With the change in the nature of this agent the elevation of the temperature as well as the other so-called symptoms of fever must also change in their appearance. We have come, then, to additional proof of the fact that the causes of fever alone will give us the clue to differentiate and recognize different elevations of temperature.

Now, before we close, we must say only a few words as to the influence fever has upon the organism as a whole. At first the opinion was universally adopted that fever is a beneficial reaction of the organism against some disease. Liebermeister first expressed the opinion that a high temperature is injurious to the organism, and has to be combated. But lately, on Pflueger's initiative, experimental investigators are appearing to prove that a high temperature benefits the organism. The most important among these works is that by Loewy and Richter, who have endeavored to show that animals withstand better different bacterial infections (diphtheria, pneumonia, etc.), after having undergone the Sachs-Aaronson brain-prick than without it. This question is by no means settled as yet, but the truth must certainly lie somewhere between the two extremes. While high temperature in general is certainly injurious to the organism, an ordinary febrile temperature does no harm to it, and very probably often does some good. Liebermeister's opinion, therefore, that every rise of temperature must be fought against and reduced by all means, is wrong; especially since, as we have mentioned already, none of the above-mentioned changes accompanying fever is in any way influenced by antipyretics.

FOREIGN BODIES OF THE NOSE AND EAR.*

By PERCY FRIDENBERG, M.D.,
ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY, ETC.

THE recognition and removal of foreign bodies which have found their way into such easily accessible regions as the nasal cavities and the external auditory canal seem so simple a matter, the underlying principles of treatment are so well established and, as it were, self-evident, and the technique of treatment is so uncomplicated, that the presentation of this subject *in extenso* might give the impression of being to some extent a gratuitous effort. If, nevertheless, I proceed to give you a few rather elementary suggestions and to detail clinical facts which are, or should be, as well known to the general practitioner as to the aural surgeon, it is because experience shows that, just in this class of cases, men who ought to know better often show a surprising ignorance; that those who actually do know better sin against their better knowledge both in overlooking foreign bodies through superficial examination and in using improper methods for their removal, and that even some of our honored teachers, as I have had occasion to observe, do not always practice what they preach.

The peculiar instinctive tendency of young infants to stick into their mouths anything movable they get hold of, from a toe or a finger to a buttonhook or a spool of cotton, is well known. Children of slightly larger growth go up a step in the process of self-recognition, and discover that they have in the nose a most convenient receptacle for the storing of such valuable objects as beans, buttons, glass beads, or fruit-seeds. This probably occurs much oftener than it is brought to the knowledge of the physician or even of the nurse, and in many cases, doubtless, a small foreign body comes out spontaneously, is ejected by sneezing, or perhaps even removed by the little one's own efforts without anyone being the wiser. Among the hysterical and insane, again, this is occasionally observed, while finally we have to deal with foreign bodies originally introduced into the nose with therapeutic intent—for instance, to control hemorrhage—which, strange as it may seem, are forgotten and left *in situ* or perhaps more frequently partially overlooked and not entirely removed.

Besides the inanimate bodies above mentioned, we must consider the possibility of living insects or of their eggs or larvæ getting into the nasal cavities; rare accidents with us, as in all temperate regions, but not at all infrequent in the tropics. Foreign bodies may enter the nose by the nostril, the usual way; through the choanæ from the nasopharynx, even without paralysis of the soft palate, as in violent vomiting or gagging, or finally by penetrating the soft parts and bony structures and entering directly from without, which, of course, presupposes severe traumatism, such as a bullet-wound, stab, or blow.

The presence of a foreign body, even in adults, is not always suspected, and symptoms which are often quite obscure are not correctly interpreted and referred to the real cause. Nasal obstruction is, as we know, borne with surprising patience, even with coincident purulent discharge, so that it is perhaps not so surprising to hear of the detection and removal of foreign bodies which have been retained for years. The symptoms are usually quite marked, and nasal obstruction is the most prominent and annoying, affecting the respiration and giving the voice a nasal twang. This is caused first and foremost by the mechanical action of the mass of the foreign body, but to a minor degree as well by the reactive congestion and swelling of the nasal mucous membrane, particularly of the turbinate bodies, and by increased secretion due to irritation which naturally, having no free exit, accumulates, decomposes, and, further irritating the secreting surfaces, completes the vicious circle. As secondary evidence of obstruction we may have œdema or inflammatory swelling externally in the soft tissues of the face about the nose and suffusion of the eye. A sense of fullness, or actual headache, with pain of a neuralgic character in the nose, cheek, and orbit, may be present with various sympathetic disturbances of the eye and ear, such as lacrimation and photophobia, tinnitus aurium, and otalgia. Attacks of sneezing may occur, and quite rarely, in specially susceptible individuals, nervous reflex manifestations, varying from mild facial twitching, vertigo, nausea and vomiting, to spastic torticollis (Rohrer), and epileptiform attacks in a child (Wertheimer) have been observed.

After remaining *in situ* for some time without being noticed, small foreign bodies may increase in size by imbibition of fluid from the nasal secretion, as in the case of peas, beans, or other porous bodies; or by incrustation from the same source with a deposit of crystallized salts, usually carbonates and phosphates. In the latter case we then have the stony-hard, irregular nasal calculus or rhinolith, which in shape adapts itself to the nasal passages, but, steadily growing, exerts ever-greater pressure on its confines, and may at last cause deviation of the septum, or even a large perforating ulcer, and actually depress the floor of the nose, so that palatal bulging becomes evident, or, as happened in a case reported by Nolte, the roof of the mouth is perforated at the junction of the hard and the soft palates.

The recognition of a foreign body is not difficult in recent cases, especially when the history is unequivocal and points directly to the cause of the trouble. In such cases the presence and position of the foreign body and its nature, as far as that is of importance for the choice of methods of removal, may be determined quite readily. In children under seven, unilateral obstruction with marked mucopurulent discharge may, with probability, be ascribed to a foreign body, as affections of the accessory sinuses can be excluded. In adults, similar symptoms should at least lead us to suspect a like cause. Sinus empyema would, it is true, be accompanied by stenosis of the corresponding nasal passage and by purulent discharge, but this rarely complete stenosis is due to congestion and swelling of the turbinate bodies, is not constant, and tends to disappear or at least to become much less after the application of cocaine or of suprarenal extract, while the pain and local tenderness characteristic of this affection should lead to differentiation. Careful rhinoscopy with good light, thorough cocainization and exploration and palpation with the use of the probe are of great importance. In little children, cocaine anæsthesia may not be sufficient, and if there is much fear or restlessness—and this we may expect if instruments are to be passed into the nose—a whiff of chloroform or ethyl-chloride may have to be administered. If the obstructing mass offers a hard surface and some resistance to the probe, we have to deal either with a foreign body, necrotic bone, osteoma, or a rhinolith. Necrosis of bone is generally accompanied by intense fetor, deformity of nasal cartilages and bones, by hemorrhages, by less marked obstruction, and generally scanty or absent secretion, and the obstructing mass is usually less easily movable than a foreign body, and communicates through the probe the sensation of denuded bone,

*Read before the Metropolitan Medical Society, April 23, 1901.

besides which its attachment to the nasal walls can usually be made out. An osteoma may generally be excluded by careful probing, and mapping out the boundaries of the obstructing mass, with consideration of the entire clinical picture. An attempt at extraction may be necessary to assure the diagnosis. Differentiation between a rhinolith and a hard foreign body is not feasible except, perhaps, in an undoubtedly recent case where the history as to the cause is clear; nor is it of therapeutic importance.

It is well to remember that both foreign bodies and rhinoliths may be covered by mucus or pus, or actually by a sort of pyogenic membrane, and may escape detection unless this layer is wiped away with a tuft of cotton wound on an applicator, and the probe used again.

Treatment.—It is well to try simple measures at first. After spraying the nares with a four per cent. to six per cent. solution of cocaine, and applying adrenaline solution or suprarenal extract in fluid or powder form, the unobstructed nostril should be closed and the patient instructed to blow vigorously. This alone, in some cases, is sufficient to dislodge a small, smooth, or unimpacted body, such as a button or cherry pit. In children who are too young to blow the nose themselves, we may use inflation with a Politzer bag, blowing air in through the free nostril. Mackenzie advises the introduction of a stream of water through the unaffected side to flush out the obstructed passage. This advice is hardly safe, however, as the stream of water must fill the nasopharynx with considerable force if it is to have sufficient impetus to loosen and expel a foreign body through the other side. The orifice of the Eustachian tube may be forced open by such a procedure, and water plus nasal secretion forced into the middle ear with unpleasant results. Direct syringing of the obstructed cavity through the anterior nares or, better still, through the pharyngeal opening with a post-nasal syringe or curved catheter is a safer plan. Sajou's method of clearing the nasal passage by drawing a tampon of moistened gauze through it from behind may be of service at times, especially if the foreign body has lodged or been pushed far back toward the posterior nares. If these manœuvres fail, direct extraction by instrumental aid must be tried. A strong probe bent over at the tip, a foreign-body hook, a wire loop, or a blunt curette may be passed between the foreign body and the wall so as to draw it forward and out, or at least to loosen it so that it may be grasped between the hollowed jaws of a slender angular forceps and extracted with a slightly rocking motion and as carefully and as gently as possible. If the mass is too large to pass out at the nostril we may have to push it back into the nasopharynx, after cocainizing the mucous membrane of these parts. The patient's head should be inclined sharply forward, or a finger passed into the nasopharynx to prevent the foreign body falling into the glottis.

If the dimensions of the foreign body are such that it cannot even be pushed into the nasopharynx, an attempt may be made to break up the mass by the use of crushing forceps, rongeur or cartilage scissors, or, in exceptional cases, to shrink it by repeated application of the galvano-cautery point. Very large rhinoliths may be reduced chemically, if subject and physician have sufficient patience, by the application of concentrated acids, as suggested by Voltolini.

Gauze and cotton plugs which have become soaked with blood and secretion easily escape detection, and the latter are removed with some difficulty if adherent, as they shred off and come away piecemeal with the forceps. The use of cotton for deep plugging cannot be too strongly deprecated, and when gauze is used we should know just how many pieces have been inserted.

Epistaxis, more or less copious, may interfere with instrumental extraction, and this must be controlled if we wish to proceed safely and thoroughly. The preliminary application of suprarenal extract and cocainization will be of material assistance in this respect, as well as in diminishing swelling, and so giving a larger channel for the removal of the foreign body.

In the rare event of insects or maggots having entered the nose, syringing out with large quantities of weak bichloride solution (1:10000), carbolic acid (one per cent.), tobacco-water, or chloral hydrate, turpentine inhalations or insufflation of calomel have been suggested to kill and dislodge the troublesome visitors. The use of chloroform injections, pure or in mixture, with an equal bulk of water, seems to have met with universal approval, and to have superseded the other solutions. The injection is, however, painful, and may be preceded by a general anæsthetic, preferably chloroform itself. The inhalation alone is sometimes quite sufficient.

In the after-treatment of all these cases, attention should be paid to two important points, the cleansing of the nasal passages and the prevention of post-operative hemorrhage and infection.

Foreign Bodies in the Ear.—From time to time it falls to the lot of the general practitioner to be called upon to treat certain of the more common affections of the ear, and few of them require at times more manipulative skill than do cases of foreign bodies in the auditory canal.

The common belief is that the presence of a foreign body in the ear, without reference to its character or its mode of lodgment, is necessarily a serious matter. It is hardly necessary to say that this belief is groundless. Usually, unless the object be tightly impacted in the canal, or be pressing upon the drumhead, or of an irritant or caustic nature, its presence may cause slight discomfort, if any. This is of twofold importance. It imposes upon us the obligation of seeing to it that our remedy, or remedial attempts, be not worse than the disease. Secondly, as in most cases there are no immediate ill consequences, hurried and unskilful attempts at removal, whether undertaken by layman or physician, are to be discouraged. The need for interference is seldom so urgent that time cannot be taken to obtain expert assistance, and it should be borne in mind that the cases which prove to be serious and tax the ability of the aural surgeon are almost invariably those which have previously been subjected to the well-meant but injudicious efforts of the unskilful. As Politzer has very truly said, "The consequences attributed to the foreign bodies are, with very rare exceptions, provoked by unskilful attempts at extraction, undertaken by unpracticed hands."

If, in accordance with most writers, we exclude cerumen plugs from the scope of our consideration, foreign bodies of the ear are not common, either in general or special practice. Roosa gives somewhat less than one per cent. in a hospital practice embracing 11,000 cases, and twelve per cent. in about 5,000 private patients.

The presence of a foreign body in the ear may be ascertained quite accidentally in the course of a thorough aural examination. It is surprising what tolerance is shown in regard to the ear, and with what equanimity, worthy of a better cause, affections of this organ, unless they cause marked pain, are allowed to go uncared for. Even foreign bodies

which are large enough to affect the hearing seriously may remain undisturbed for years.

Foreign bodies may obtain entrance into the ear in a variety of ways: Those most frequently found have been introduced intentionally, as by children in play. The favorite objects are, as before, stones, pebbles, glass beads, buttons, "spit-balls," seeds, and pits. Adults, with the more serious purpose of relieving itching, removing cerumen, or perhaps at times of stimulating mental processes, insert twisted paper, spills, toothpicks, penholders, etc., which fortunately are not apt to be retained, except, in rare instances, by splintering. Other foreign bodies may get into the ear by accident, as in swimming, or be propelled with some violence, as small projectiles, chips of stone, etc. Animate foreign bodies may enter by their own efforts, as in the case of mature insects (bed-bugs, roaches, ticks, or flies) during the heated term, and again more frequently in the tropics or while camping out in the woods, and at other times during sleep in filthy quarters, or larvæ may be hatched from eggs deposited in the meatus by flies attracted to a running ear by the smell of pus.

Symptoms.—Even more varied than the species of foreign bodies are the degrees of severity in the disturbances, subjective as well as objective, to which they give rise. The gravity of the injury depends not only on the nature and size, the shape and consistency of the foreign body, but more particularly on the degree of force with which it has entered the ear, and the depth to which it has penetrated, either spontaneously or by unsuitable attempts at removal.

Inanimate objects, if smooth and not large enough to cause pressure (such as glass beads, buttons, etc.), which are not introduced very deep or with much force, generally cause no pain at all, so that in the absence of a clear etiological history, their presence may be suspected only on account of ringing in the ears, slight deafness, or more often the feeling of fulness in the ear, and the peculiar sensation of "autophony" or subjective vibration and relatively increased bone conduction, which give to one's own voice and sound of swallowing the disagreeable jarring sensation we feel when there is wax or water in the external meatus.

Bodies which wound or irritate the wall of the canal may caused more marked pain, while at times those which have caused no perceptible local changes have sufficient effect on the sensory nerve terminals in the ear to set up reflex manifestations, particularly cough of a hacking, dry, irritating nature, the so-called "useless" cough. This seems to depend more on individual susceptibility than on the character of the foreign body, being more frequent in children; and we occasionally notice that even the slight and temporary irritation of the canal-wall or tympanum by the touch of a probe, curette, or applicator may cause a sharp fit of coughing.

Other reflex phenomena, such as vomiting, hiccough, trigeminal neuralgia, paræsthesia, dysphagia, facial tic, and even epileptiformic seizures have been reported in literature, but are extremely rare

Living insects free in the external meatus cause great discomfort and annoyance by their movements, but actual pain is the result of the animal striking against or attaching itself to the drum membrane; the suffering then may be intense and radiate to the occiput and temple. Pain is, of course, a constant symptom wherever the foreign body has been driven into the meatus with sufficient force to wound its walls or the drum membrane. Perforation of the latter may be followed by middle-ear infection with the intense pain, throbbing, and general malaise characteristic of acute inflammation of this cavity. This is particularly apt to be the case with sharp-pointed objects, practically never aseptic, which have lacerated the drum and entered the tympanic cavity, often dislocating the ossicles. In fact, the foreign body may disappear behind the tympanum and remain in the middle ear, or even enter the Eustachian tube.[1] Foreign bodies which swell easily may, if they remain *in situ* for a long time, gradually produce considerable dilation of the canal, without causing much pain. Toynbee reported a case in which such an effect had been produced by the retention of a cotton plug.

Diagnosis.—We must not forget that the sensation of a foreign body may be caused by various forms of external otitis or by irritation of discharge, and that the patient may in good faith believe in the presence of one when there is actually nothing tangible. Again, a small foreign body may have entered the ear and fallen out again without the patient's knowledge, so that the first object of examination is to determine whether there is any foreign body at all present. Inspection will at times establish the diagnosis, but in every case we must bear in mind the importance of a careful examination under the best focal illumination possible, want of which is probably the most fertile source of unsuccessful efforts at removal and of consequent damage. Under no circumstances should we permit ourselves to introduce probes, hooks, or forceps, and to feel about for the foreign body, unless every movement is controlled and guarded by the eye The result would almost inevitably be to push the foreign body still farther into the canal, or even to perforate the drum.

When carefully used, together with inspection, the probe is one of the most useful diagnostic aids, and may be of much service in determining the consistency and mobility of the objects revealed.

We may overlook a foreign body:

1. If the drum has been perforated and the foreign body has passed into the tympanic cavity. Careful examination with the mirror may then reveal a perforation, and often a bulging of the drum, or dislocation of the ossicles and distortion of the membrane by pressure of the foreign body, and the probe will impinge upon a more or less unyielding mass behind the drum—perhaps in the attic.

Secretion or exudate may conceal the perforation, and unless we have removed this deposit, the fact of perforation may escape our notice. Persistence of the symptoms or development of others pointing to acute otitis media may finally necessitate a free paracentesis of the drum, which exposes the foreign body and clears up the diagnosis.

2. If the canal walls are occluded by swelling of the soft parts from an otitis externo, due to injury by a foreign body, or more often to rough and unskilful attempts at extraction. This may be overcome by the use of a bivalve speculum, if necessary under general anæsthesia, or in the absence of urgent symptoms we may wait for the swelling to go down, assisting by the application of leeches to the tragus and to the back of the concha, the instillation of astringents, and the use of hot moist compresses.

3. If the foreign body is incorporated with cerumen. The detection is then of minor importance therapeutically, as the removal of the plug—pref-

[1] Deleau cites a case in which the foreign body, an agate, which had gotten into the tympanic cavity, was finally dislodged by syringing forcibly from the nose through an Eustachian catheter

erably by ... in ... indicated in any case. The probe ... reveal the true nature of the mass.

... When the sinus of the auditory canal is very deep and the foreign body lies in it. The sinus is a hollow in the floor of the meatus, directly in front of the drum. Its outer wall is almost at right angles to the axis of the canal. If the foreign body does not appear when the patient's head is sharply inclined to the unaffected side, or with the patient lying down, we may introduce a small middle-ear mirror, and so get direct inspection. We may reach a practical result more simply and rapidly, however, by thorough syringing, which will bring out a foreign body if there is any there.

Treatment.—In most cases we will accomplish our object by freely and repeatedly syringing out the ear with warm boric-acid solution, to which a little soap or lysol may be added as a lubricant. We should always rely primarily upon the syringe as the best means of removing the foreign body, and be prepared to persevere with it. The chief contra-indications to the use of the syringe, none of them absolute, are the presence of a large perforation in the drum through which the foreign body might be washed; a sharp-pointed body which might wound the drum, or the development of severe nausea. In syringing, the curve of the membranous canal must be overcome by drawing the auricle backward, outward, and slightly upward (backward and downward in little children); the syringe should not be directed along the canal, but somewhat toward the upper wall of the meatus, so that the stream, instead of impinging with force upon the drum, flushes it from above downward, and a steadier double current is set up.

The patient's head should be inclined toward the affected side, so that gravitation may assist us as far as possible. In case the foreign body is soft and swells up easily by imbibition, it may become more tightly impacted at first when we syringe with aqueous solutions.

The instillation has been advised of a mixture of alcohol and ether, which absorbs moisture from the mass, dries it out, and so causes it to shrink up or crumble to pieces. Usually this is not necessary, as hot water will, if persevered with, finally soften such bodies as peas, beans, or cerumen-covered masses to such an extent as to disintegrate and flush them out. This may be assisted by the careful use of a blunt curette or hook to pick the mass apart.

In the case of harder organic bodies impacted in the meatus, Voltolini has advised the burning out by repeated touching with the galvano-cautery point to cause them to shrink, after applying a lubricant to the external meatus, as a protective surface and to facilitate extraction.

As therapeutic curiosities we may mention the method (quoted by Loewenberg as having descended from Celsus himself) for the removal of a foreign body by pressing against it a small camel's-hair paint-brush, previously dipped in melted glue, and withdrawing this novel instrument, after the semi-fluid sticky mass had set, with the foreign body adhering; the loosening and eventual removal of a tightly-wedged cherry-pit by means of aspiration with an ear syringe attached to a rubber tube; and finally the use of irrigation by catheter from the nose. In case simple measures fail, the use of such instruments as the foreign-body hook or spoon, the wire loop, a bent probe, fine angular mouse-tooth forceps, or more rarely a snare, becomes inevitable.

I must again remind you that one and all of these instruments may cause serious mischief, unless used with judgment, that the method of application, not the choice of the instrument, is of paramount importance, and that, whatever procedure be employed, it cannot be considered really safe unless carried out with perfect care through a good speculum and with ample illumination.

In the rare event of a foreign body resisting all attempts at removal, which has penetrated so deeply or is of such a size as to give little hope of extraction by the methods cited, it may become necessary to expose freely the cavity in which the mass is wedged, and to remove it immediately, or after comminution, by suitable instruments. After preparing the region about the ear by shaving and disinfection, with as much care and attention at least as we would use in a mastoid operation, we proceed, under full asepsis, to detach the concha and cartilaginous meatus from behind. A curvilinear incision is made close behind the auricle along the insertion of the concha, extending from the mastoid tip to the supra-mastoid ridge and including the soft parts down to the periosteum. This incision may cut through the cartilaginous canal which lines the posterior bony wall of the external auditory meatus, or the canal is dissected up from the underlying tissues and its posterior wall cut through at as deep a level as possible.

On retracting the flaps, the foreign body can be grasped and removed; at times, it is true, only after cutting away the posterior wall of the bony canal or the tympanic cavity and breaking up the mass with a mallet and chisel or crushing forceps. After carefully syringing and removing all chips and spiculæ of bone, the soft parts are replaced, the entire wound closed with numerous interrupted silk sutures, a tampon of gauze placed in the canal as a drain and splint combined, and a complete dressing applied over and around the auricle.

In addressing you on a topic which is of at least as much practical importance to the general practitioner as it is to the specialist, I am well aware of having merely given a résumé of well-established views and methods, unfortunately but too often neglected. In the nature of the subject, as in the character of my experience, there has been no occasion for the presentation of anything original or striking. I may be permitted, however, if any excuse were needed on this score, to call attention to the fact that while new and important fields of pathology and therapeutics are being explored by the small body of scientific pioneers, most of us, after all, belong to the vast army of occupation, and that we too will contribute in no small measure to the practical progress of medicine if we take care of our territory, no matter how long since it was annexed, and manage it with common sense, with skill, and with fidelity.

Albuminuria of Obscure Origin Occurring in a Case of Thoracic Aneurysm.—E. B. Bostock and J. G. Emanuel report this case in detail, noting the following interesting facts: While the autopsy confirmed the diagnosis of aneurysm of the arch of the aorta compressing the trachea, the albuminuria and œdema which were present were found due to widespread lardaceous disease. They consider marked lardaceous disease as the result of uncomplicated syphilis rare, as was the condition in the reported case, which also appears to prove that lardaceous disease of the kidneys of itself does not give rise to hypertrophy of the left ventricle. The marked visceral lesions shown are uncommon in locally acquired syphilis. The case tends to prove that aneurysm *per se* does not cause hypertrophy of the left ventricle.—*The Birmingham Medical Review.*

SOME ULTIMATE RESULTS OF GUNSHOT WOUNDS CAUSED BY MAUSER BULLETS DURING THE LATE SPANISH-AMERICAN WAR.

NEW YORK
SURGEON SECOND BATTALION N. Y. S. N. G.; LATE SURGEON THE NEW YORK VOLUNTEER CAVALRY.

On my return from Puerto Rico, having been officially detailed by the Surgeon-General of the United States Army to make physical examinations of the members of the Seventy-first Regiment N. Y. V. Infantry, prior to their muster out, it was my privilege to note some ultimate results of wounds caused by Mauser bullets. Most of these wounds occurred during the attack on San Juan Hill, and demonstrate the humane nature of this special weapon, death resulting only when a vital portion of the body had been struck, or when the knowledge or the means for arresting fatal hemorrhage was not at hand.

Case I.—H. S., private, Company M, was wounded in the left knee joint. A Mauser bullet entered at the outer and upper aspect of the left patella, and struck the external condyle of the femur, slightly splintering the bone and traversing the cavity of the joint. It emerged just below the patella, the head of the tibia remaining uninjured. At the time of examination there was found slight roughening of the articular surface of the femur, and distinct crepitus was felt on active and passive movement of the joint. There were also evidences of trophic changes on the outer aspect of the knee joint, due to direct injury to the blood vessels. There was no reason to believe, either from the history of the case or from the examination of the joint, that septic inflammation had occurred at any time. The range of motion (flexion and extension) was about two-thirds normal, with every indication that the perfect use of the joint would be regained. In this case recovery had in all probability been delayed by the patient's condition of severe malarial cachexia.

Case II.—E. R. P., private, Company M was struck by two Mauser bullets. The first entered the posteroexternal aspect of the left thigh, about 15 cms. below the tip of the great trochanter, passed through the muscles on the outer side of the thigh, punctured the external condyle of the femur, and emerged 1¼ cm. above the outer and upper portion of the patella (knee in extension). The second bullet had its wound of entrance 1¼ cm. above the wound of exit of the first bullet, entering the femur, and emerged just below the patella, skirting the outer part of the joint. There was no evidence of septic inflammation having occurred, and the use of the joint was complete at the time of the examination.

Case III.—L. I. D., corporal, Company M, received wounds from four Mauser bullets. The first entered the anterior wall of the chest, 3¾ cms. to the inner side and 1¼ cm. below the right nipple, ran through the skin, subcutaneous tissues and muscles in this region (not entering the thoracic cavity), and emerged opposite the tenth rib in the mammary line of the same side. Recovery was complete. The second bullet entered the anterointernal aspect of the middle third of the right thigh, ran through the muscles, and emerged 10 cms. below and 5 cms. to the inner side of the wound of entrance, recovery being complete. The third bullet entered the front of the same thigh 15 cms. above the upper border of the patella, and the wound of exit was situated 7½ cms. above and 3¾ cms. to the inner side of the mid-point of the upper border of the patella (knee in extension). Recovery was also complete. The wound of entrance of the fourth bullet was at the inner side of the knee joint of the same side, and the bullet remained embedded in the joint, from which it was later extracted. The range of motion in the knee joint at the time of examination was found to be only slightly impaired. In all four of these wounds in this one man there was neither history of, nor were there any signs of any delay in the healing process caused by septic inflammation. None of the large vessels was injured, and the hemorrhage was very slight, the wounds being small and clean cut. The general was on the skirmish line, and in the act of mounting when he was struck by these four bullets in quick succession. He said that the pain was slight, and that he continued to look after his squad on the skirmish line for some time after.

Case IV.—J. G. P., private, Company F, was hit with a Mauser bullet, which entered the front of the right instep, and emerged from the sole of the foot. The wound healed promptly, but he experienced slight muscular pains in the right leg, which were undoubtedly the result of the injury. The function of the foot was perfect.

Case V.—F. H., private, Company F, a Mauser bullet entered 3¾ cms. to the left of the tip of the spinous process of the third lumbar vertebra. There was no wound of exit, and the course of the bullet could not be determined. There was no evidence of any internal injury, and recovery seemed complete.

Case VI.—J. M., private, Company M, received a gunshot wound of left knee. A Mauser bullet entered the outer aspect of the knee joint, and emerged to the inner side of the joint, the bullet grazing the posterior surface of the patella. The injury to the bones was practically nil; but the irritation caused by the passage of the bullet set up a productive inflammation in the joint, which resulted in the formation of adhesions, thus causing a limitation of motion. These adhesions are gradually breaking up the active and passive movements, and the complete function of the joint will in all probability be fully regained.

Case VII.—J. S. L., quartermaster-sergeant, Company B. A Mauser bullet entered the right thigh 10 cms. below and 5 cms. anterior to the tip of the great trochanter, and emerged from the thigh 8¾ cms. below and 2½ cms. behind the same point, passing through the muscles on the outer aspect of the thigh. The wound healed promptly, without any septic inflammation.

Case VIII.—W. B. C., private, Company B. Mauser bullet entered the temporal bone on left side 3¾ cms. behind and ¾ cm. below the external auditory meatus, and emerged from the buccal cavity, after having torn away the last two lower teeth on the left side, and the right upper and lower middle incisor teeth and the lower right lateral incisor tooth, in all a loss of five teeth. The course of the bullet must have been as follows: Entering the posterior part of the mastoid portion of the left temporal bone, the bullet traversed the bone just internal to the mastoid cells in the region of the digastric fossa and the groove for the occipital artery, then passing by the carotid arteries, avoiding the other important vessels and nerves in this region, passed above and to the outer side of the transverse process of the atlas into the buccal cavity, striking the last two lower molars on the left side, and emerged from the mouth after striking the right upper and lower middle incisor and the lower right lateral incisor teeth, breaking them off at their roots. At the time the man received the wound the hemorrhage was not profuse, being limited almost entirely to oozing from the mucous membrane of the pharynx, and the shock was not great. When the man presented himself to me for examination, he complained only of the loss

of his five teeth, and said he was rather nervous, and subject at times to slight headaches. His hearing on the left side was normal. Considering the course of the bullet, the manner in which the latter escaped the important vessels and nerves seems almost miraculous. It certainly demonstrates that the bullet from the Mauser rifle, when not diverted in its course, causes almost no damage to the tissues adjacent to the immediate line in which it travels, the tearing and laceration of the soft parts being almost nil.

CASE IX.—J. M. N., corporal, Company K. A Mauser bullet entered 2½ cms. below the base of the spine of the scapula on left side, passed through the bone, pierced the apex of left lung, and emerged from the front of the chest 3¾ cms. to the inner side, and 1¼ cms. below the tip of the coracoid process between the first and second ribs. The same bullet having been deflected upward, entered the neck at about the apex of the left submaxillary triangle, passed through the soft tissues into the mouth, removing two teeth in its exit. Although it is not mentioned in my notes of questions asked the man at the time I examined him, yet, when he was shot, he was probably leaning his head over his rifle, taking aim. The man neither suffered from severe shock nor hemorrhage, and the wound healed promptly. He said he had nothing to complain of save the loss of his two teeth, and he thought that he could get along very well without a pension from the government.

CASE X.—C. A., corporal, Company K. A Mauser bullet entered the back of his arm 5 cms. above the tip of the olecranon process of the ulna (arm in extension), passed through the lower extremity of the humerus in the region of the trochlear into the joint, leaving the forearm 7 cms. below the internal epicondyle of the humerus. At the time of my examination there was only a very slight interference with extreme flexion of the joint, and the use of the arm was sufficient for all practical purposes.

CASE XI.—D. C. McC., private, Company E. A Mauser bullet entered the head of the right tibia, and emerged on the outer side of the knee joint, avoiding the patella. The head of the tibia had been punctured, and there was no splintering of the bone. On examination, I found that there was some crepitus on movement of the joint, but flexion of the knee was only very slightly limited.

CASE XII.—J. J. McD., first sergeant, Company F. The bullet from a Mauser rifle entered the antero-external aspect of the greater tuberosity of the humerus, went diagonally through it and the corresponding portion of the shaft of the bone, and emerged at the posterior side of the arm at the junction of the upper and middle thirds. There had evidently been no splintering of the bone, and the function of the arm was perfect.

CASE XIII.—J. E. M., private, Company F. A Mauser bullet struck him in the outer and upper portion of the left buttock, and the bullet was extracted from the femur by an incision 5 cms. below point of entrance. There was no loss of function, and no evidences of splintering of the bone or laceration of the soft parts.

The two following cases, although bearing no relation to the subject, may be of some interest.

G. J. H., private, Company D, told me at the time of the examination that, during the engagement of San Juan Hill, one of the guns of Captain Capron's battery was fired from a slight eminence behind and somewhat above him. He said he felt stunned for a few minutes, and as soon as he could collect his thoughts, he noticed that he was deaf in his right ear. Thinking that it was merely temporary, he gave it little attention. The deafness, however, has persisted, and on examination it was found that the concussion from the discharge of the gun had caused complete dislocation of the ossicles of the ear.

G. F. F., private, Company F. A shell from one of the guns of our own artillery exploded within a few feet of this man, and a fragment struck him on the right side, crushing the fifth to the twelfth ribs, inclusive. This resulted in an irregular bulging of the right side, and marked lateral curvature of the spine (convexity to the right). The man suffered severe pain for some time after, but this has entirely disappeared. The injury healed promptly, but left a deformity which interferes with the use of the right arm, and there is partial paralysis of the fourth and fifth fingers of the right hand. The expansion of the right lung is irregular, and there are signs of firm pleuritic adhesions binding the lung to the chest wall, which moves only slightly with respiration. The man is disabled for the performance of any form of hard manual labor.

In the foregoing cases, with the exception of the last two, we note, that, owing to the great velocity, the rapid rotary action, the hardness of the outer shells, the shape and the weight of the bullets from modern small-bore rifles, of which the Mauser is a fair example, and the long ranges which generally obtain in modern warfare, most of the wounds, on account of their trivial nature (the wounds of ingress and egress being usually small), heal rapidly, in the majority of cases, without suppuration. We also note that tearing and laceration of the soft parts, as a rule, are slight, and that when bones are struck they are more often punctured or grooved than broken or splintered, which was the case with the old leaden bullets, with their great explosive effect and slight penetrating power. Primary and secondary hemorrhages are correspondingly reduced.

Certainly these and the many other cases on record show that the change to the use of small-bore rifles by the armies of the civilized world has proved to be a great blessing in modern warfare.

A NEW OPERATIVE PROCEDURE FOR TREATING INFLAMMATION OF THE POSTERIOR PART OF THE EYE.

BY S. BUSBY ALLEN, M.D.,
NEW YORK,
ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

IN treating inflammation of the lids, cornea, iris, and ciliary body, amongst our most potent remedies is temperature. Without the use of hot water, without the use of cold ice cloths, how limited we would be in the treatment of these diseases! With them, intelligently used, in conjunction with other remedies, what wonders are accomplished!

If, without injury to the ocular or orbital tissues, these remedies could be applied to the posterior part of the eye, might we not hope for like happy results? The field seems broad and hopeful—indeed, so full of promise as to justify any amount of work, and the assumption of considerable risk. The risks are at the most problematical. There are no certain contra-indications, no visible lions in the way. If, after prolonged and severe experiments upon rabbits, we find no ill effects, would we not be justified in trying cautiously the effect upon the human eye, threatened with partial or total loss of vision. And when we consider the paucity of our remedies for these inflammations, that in many of these diseases we are little more than spectators, watching an eye go from bad to worse, or perhaps to total destruction, unable to be of much real service, we are emboldened to advance, though at some risk. Tenon's capsule offers a sure, easy, and familiar way, for reaching the

nerve and its head, the very heart of these troubles. The vagina offers no surer road to the gynecologist in his treatment of the womb and its appendages.

May we not use Tenon's capsule for hot water injections as the gynecologist uses the vagina, or the aural surgeon the external canal for disease of the attic, antrum, middle ear, and mastoid.

Let us consider more in detail the proposed procedure and the possible dangers attending it. In regard to the anatomy of Tenon's capsule, it is not necessary to deal with the various refinements of dissection which are still a matter of dispute.

It is enough for us to know that here we have a delicate membrane, separating the ocular from the orbital tissues, extending from near the edge of the cornea to the optic nerve, crossed by bands of connective tissue, which are particularly numerous at the posterior part. Being a lymph space itself, it is connected with other lymph spaces around the optic nerve.

That though the capsule moves with the eyeball, the ball has some motion within the capsule, more especially if the ball has a short anteroposterior diameter. That on one side of this space we have the tough sclera, enclosing the more delicate tunics of the globe; on the other side, we have a mass of fat, pierced and ramified by nerves and blood vessels.

That this fat in front is hard, but at the posterior part, in the cone formed by the recti muscles, this fat tissue is exceedingly delicate, almost fluid.

In this operative procedure there are two sources of danger. First, the necessary technique of the operation, viz., opening the capsule, passing the catheter back to the nerve and maintaining it there; the pressure of the water, if too great, stretching, dissecting, perhaps tearing, and penetrating parts not desired.

Second, the temperature of the water; if it be too high, what damage might it do to the sclera, to the sheath of the nerve, to the head of the nerve, to the choroid and retina? Would it disorganize the vitreous, would it have any effect upon the capsule or lens? Would it disorganize the delicate fluid-fat at the posterior part? Could it do any injury to the other orbital vessels? Lastly, what would its effect be upon the epithelium of the capsule itself? This seems to me to sum up about all the dangers we might anticipate.

What are the cases or class of cases we might, reasoning from analogy, expect would be benefited, and what are the cases or class of cases in which the operation is not indicated? It would be indicated, first, in those cases over which at present we have very little control. It is not indicated, and would not be justified, in those cases over which we have control, and look with reasonable hope for recovery, or those cases that are due to an especial cause, and are constitutional.

It is evident that when the inflammation is due to poison, as in syphilis or rheumatism, or in albuminuric retinitis, diabetic neuroretinitis; when serious arterial changes have taken place; when alcohol, tobacco, lead, zinc, copper, or other poison can be assigned as causative; when the disease is intercranial, as meningitis, whether simple or tuberculous, or a neoplasm; acute otitis media; abscess of the brain; or when due to periostitis of the orbit, or orbital tumors: to empyema of the frontal sinus; or caries of the teeth; or malformation of the skull; to nipping of the nerve in fracture of the sphenoid; to intermittent fever; severe hemorrhage, anæmia, sunstroke, acute myelitis, grip, chlorosis, menstrual disorders, sunstroke, or acute, exhausting diseases, as pneumonia, typhoid, typhus, measles, and scarlet fever—it is evident that in inflammation due to these causes the proposed procedure would be but tentative, and, in some cases, clearly contraindicated.

But even when this treatment is tentative, if it be only effective, its value can scarcely be overestimated. We should remember always that the danger point is the head of the nerve, that an amount of inflammation at this point will certainly be followed by atrophy; a like inflammation further back might not have any ill effect. The head of the nerve is its most vascular part, and surrounded as it is by the tough, unyielding sclera, and having behind the lamina cribrosa is the point of danger. A choked disc always recalls to me cases of strangulated hernia; if the swelling is great enough or prolonged enough, more or less of the nerve will be dead.

Here, then, a tentative treatment might serve to lessen or hold in check an inflammation until the constitutional treatment took effect, as in syphilis and rheumatism, or until the system had eliminated poison, as in case of alcohol, tobacco, etc., or as after debilitating diseases, when we would have time for hygiene and tonics to do their reparative work. But, frankly, how many of these cases originate from causes unknown to us? How very many of them are idiopathic! Take a case of neuroretinitis of idiopathic origin; the usual course is to assume that it is due to syphilis, and load the circulation with the iodides; if the disease grows worse, we stop the iodides and give tonics. The patient gets well, or the inflammation is followed by atrophy, and partial or total loss of vision. In either case what have we contributed toward the result?

In these cases, we have been posing as specialists, without giving any special help. Take one of these cases of neuroretinitis, extending to and involving the retina and choroid; at first the back part of the vitreous, then the whole of the vitreous, the ciliary body, iris, and Descemet's membrane, becoming in fact a uveitis. While this inflammation is confined to the posterior part of the eye, how little effect we can have upon it! When it has reached the anterior part of the eye, how vigorously we attack it with hot water, and with what palpable results! In fact, we may almost say, we can control the inflammation.

Now, why could we not extend the attack to the head of the nerve—the danger-point—the back part of the eye, before the damage has been done? Then by adding sodium chloride to the water, sufficient to raise its specific gravity higher than that of the blood, we have all the conditions for osmosis.

In this connection, let us recall the openings from Tenon's capsule into the lymph spaces around the nerve, remembering that these lymph spaces are continuous with other lymph spaces that pass forward through the vitreous and the suspensory ligament to the canal of Schlemm; that, in fact, a very network of anastomoses is maintained between these lymph spaces and other lymph channels, along the venæ verticosæ and ciliary nerve lymph space, and that these again communicate with the perichoroidal lymph spaces, between the sclera and the choroid, and these again with the comparatively larger lymph spaces between Tenon's capsule and the sclera. In view, then, of these numerous avenues of drainage, of depletion, what would be the effect of these hot saline injections upon glaucoma, or detachment of the retina?

It is evident a most powerful effect would be produced, either for good or for ill. In cases where we have an accentuated second aortic sound, with tortuous arteries, hard radials or carotids, a history

of asthmatic attacks with or without renal complication—in short, indications of arteriosclerosis—the use of such a powerful agent as hot saline injections would be either contraindicated or should be used with the greatest circumspection.

Just how this agent acts has never, I think, been clearly shown. From what I read of the action of hot water on the tissues, I was led to believe that when the tissue was submitted to water at a temperature of 115° to 118° F., for the first five minutes, there was a determination of blood to the parts, the parts becoming rosy, the vessels full, especially the arteries and capillaries, vasomotor relaxation taking place; that after about five minutes, the vasomotors are stimulated to contraction, the parts becoming blanched and shrunken. From my own observation, I believe these views are incorrect, that they have been generally accepted because no one has taken the trouble to examine just what action hot water has on the tissues.

I have tried to determine this action by taking large numbers of people and submitting them to the experiment of holding the hands immersed in the water at different temperatures.

I first tried a number at 110° F., or just a little lower; another group at 114° and the last group at a temperature as near 118° as possible. The hands were kept immersed for from fifteen to twenty minutes. It is not possible to submit the tissues to water at a greater temperature than 118° for any length of time, and water at 125° or 130° can be applied only momentarily to external parts. But at 130° and above, its action becomes really caustic. What its action is upon the circulation at this high temperature does not concern us for the purpose we are now considering.

For injection, whether into the vagina, the ear, or the capsule, a temperature higher than 118° or 120° F. is out of the question; it would be intolerable to the patient, and all the good that has been accomplished has been by the use of hot water, at a temperature below 118°. Probably most vaginal injections are taken at 112° to 114°; the direction given to the woman is to take them as hot as she can bear them. As the water flows out over the sensitive vulva, it is evident the temperature could not be higher than 115° to 118° at any time, and that most of the injection is near 112° or 114°. Of course, at a single injection the water will vary several degrees, even when great care is taken. I found that the effect upon the tissue was similar, differing only in degree, whether the water was 100°, 114°, or 118°, or higher. For the fifteen or twenty minutes the hands were immersed there was a determination of blood to the parts, the parts became rosy and swollen; finger rings that were loose became tight, and the skin bulged up around and over the rings that had been at all tight. Pressure on a point blanched the tissues for several inches; around the point of pressure there was vasomotor relaxation. What would have been the result had the immersion continued longer I am unable to say. Fifteen or twenty minutes' injection is what we are familiar with, and upon that basis we are working now.

It is not our purpose to deal with the fine physiological problems, caused by the action of the water. We know it determines a rush of arterial blood to the parts, and drives the venous blood out, thus relieving stasis, improving the circulation, establishing a more healthy metabolism, and an absorption of exudates.

These are the results we hope for, and hope to obtain without damage to the parts. That no damage results from the use of these injections upon the rabbit's eye, I have proved by repeated experiments. At first I gave an injection only every two or three days, as the rabbits were some time recovering from the effects of the anæsthetic. When, however, I found that I could operate without giving a general anæsthetic, I increased the frequency of the operations until I gave them daily for seven consecutive days. The rabbits were kept quiet by being laced up in a corset made for the purpose, extending from the head down over the hind legs. When they were laced up in this contrivance, having cocainized the eye, I could proceed without any trouble; unless some one made a sudden start, or the water trickled into their noses, they would be perfectly quiet. I opened the capsule over the superior rectus, well back, to avoid the third lid, and introduced a small silver catheter, such as we use for the nasal duct, bent to fix the convexity of the globe, and allowed water at a temperature averaging about 116° F., generally under that, to run for fifteen minutes. The first two or three days the wound closed up, but after that it remained open as long as I gave the injection daily. At first there was considerable reaction, because I allowed the water to run at too great a pressure, but after that, having lessened the pressure, so as to have it flow very gently, there was little or no reaction. At first there had probably been some stretching or tearing of the tissues, causing the reaction. I submitted the left eyes of three rabbits to the experiments for a period extending over four months, and then had Dr. Callen, Dr. Cocks, and Dr. Bell examine and compare the operated with the non-operated eye; they all agreed that no change had taken place in the eye, or in any of the media. They could detect no difference between the operated and the non-operated eye.

55 East Eighty-sixth Street.

THE DISADVANTAGES OF COPPER SULPHATE IN DISEASES OF THE CONJUNCTIVA AND CORNEA.

By CORNELIUS WILLIAMS, M.D
ST. PAUL, MINNESOTA.

For many years sulphate of copper had been in routine use for every disease of the conjunctiva in which there was infiltration or hyperplasia. So common had this abuse of that remedy become that, while its use in the hands of a skilful and careful physician, such as Dr. Claiborne of New York undoubtedly is, might be productive of good results, its abuse by the many came to be the rule. The objections to the use of copper sulphate are so great, and its advantages so much less than those of other and safer remedies, that I think it should be banished absolutely from our list of remedies. There is nothing which it can accomplish which may not be done with infinitely less pain, and in a much shorter time, by other means. Mercury bichloride, for example, is so far superior to copper sulphate in trachoma, or in any chronic pernicious hyperplastic condition of the conjunctiva, that there can be no comparison between the two. The copper salt is painful, and the pain is long and will not quiet; the mercury solution, properly used, is painless and efficient. For all of those conditions enumerated by Dr. Claiborne (Medical Record, July 27, 1901) the mercury salt is preëminently adapted. Those who may not have used bichloride of mercury in trachoma, but who have had an extensive experience with copper sulphate, if they can be persuaded to substitute the mercury salt for the copper, will never, under any circumstances, return to the barbarity of copper in the solid salt.

The tendency is always toward the perfunctory

use of the remedy that has once received the sanction of high authority, and it is this perfunctory use of copper sulphate which is, in a measure, to blame for the many cases in which grave damage has ensued from its application. Instance the following case: X had a mixed infection of one eye, from a trachoma patient who had a mild blenorrhœa as well. There was, in the beginning, considerable swelling of the lids, with rapid engorgement of the entire conjunctiva. In a week the mucopurulent discharge, which had not at any time been great, had ceased, giving place to a serous transudation. There were minute facets upon the cornea, causing monocular polyopia. The conjunctiva was much thickened and succulent; it was more like plush than velvet. This condition was gradually bettered under indifferent treatment. There had been several relapses, with some small ulcers of the cornea, when, after imprudent use of the eye, and about six months after the original infection, the conjunctiva again became acutely inflamed, with corneal ulceration. The patient was then sent to New York, and was placed under the care of an oculist of that city. The patient entered a hospital, where this gentleman attended him daily. The treatment consisted in the every-day touching of the lids, as described by Dr. Claiborne, with a wedge-shaped piece of bluestone. No atropine or other treatment was employed, save iced applications to the lids, and on two occasions peroxide of hydrogen to the ulcers of the cornea. The patient remained in this hospital for about a month; the pain of the bluestone applications, lasting for a long time, he described as infernal. There came on later other and more constant pains in the eye, head, jaw, teeth, and side of the face, which were attributed by the ophthalmic surgeon to the corneal ulceration, which steadily increased during the entire time of the patient's stay in the hospital. After a month of bluestone, the patient returned to his home, where his physician found him with an iritis (which had received no treatment) of probably more than three weeks' standing, complete occlusion of the pupil, and an ulcer of the cornea, which had perforated. Glaucomatous tension supervened upon closure of the perforation; an iridectomy was done, and the eye, under very weak solutions of nitrate of silver and irrigations with mercury bichloride, got well with V = 5-200. "Beneficent bluestone" was, of course, not entirely to blame for the disaster in this case, yet I think that even Dr. Claiborne must admit that it was faithfully used by skilled hands. In all probability, had not the bluestone been used here, the outcome would have been no worse than is seen in thousands of other cases of trachoma with ulceration of the cornea which had received practically no treatment. The iritis in this case was excited by the bluestone in addition to the corneal implication, and would not have occurred had not both exciting causes been operative.

In the province of Manitoba there are very many trachomatous eyes which have been brought from Russia. They have all been treated with bluestone at some time, not always carefully, but not one of them has ever been cured by bluestone. I have seen a number of them that had been without any medical treatment for a time varying from two to fifteen years. There had been in every case successive crops of corneal ulcers; the patients had lived in many instances in straw-thatched huts, sometimes without a window, and burning manure for fuel; but, strange to say, in not one of these cases did I find posterior synechiæ, but had these eyes been subjected to such neglect, and also to the action of the bluestone, it is not credible that they would all, or any considerable percentage of them, have escaped without iritis. Corneal ulcerations alone, accompanying trachoma, as I have many times seen, produce iritis in but few instances; given ulceration of the cornea, however, and bluestone, or other similar irritation, and it would seem miraculous if the eye should escape iritis if atropine is not used.

Atropine, as everyone knows, does irritate the conjunctiva, but in my experience all eyes with corneal lesions do better with its use than without. To use copper sulphate in trachoma is to use a method which, in my opinion, has never been other than merely excusable. It is, however, a question upon which opinions may honestly differ, but to use copper on an eye with ulceration of the cornea, and not a mydriatic, is, I think, unjustifiable.

Dr. H. Knapp, formerly of Heidelberg, used to tell his students that the most heinous crime that a physician could commit was the failure to recognize, and, of course, properly to treat an iritis. Boiling oil and molten lead as a punishment, he thought, were none too severe. And in the light of my experience I am constrained to agree with him; indeed, I would go further.

I cannot, therefore, agree with Dr. Claiborne when he advocates the treatment of trachoma with ulcers of the cornea and trachomatous pannus without atropine, but think that the conservative use of atropine here to be truly beneficent; it is the indiscriminating use of atropine which has brought reproach to its door. The inconvenience of a dilated pupil and the paralysis of accommodation are as nothing compared with the ciliary spasm, the lacrymation, and the consequent increased blood inflow. Then the tonic and clonic ciliary spasm surely brings congestion of the entire uveal tract, and even though there may not follow an iritis, there must ensue a hyperæmia of the iris, nearly approaching inflammation, a vicious circle is soon established, and the disease prolonged. Much of the irritating quality of the atropine is removed by adding to the solution boric acid or chloride of sodium. I am maintaining that the proper use of atropine in conjunctival and corneal affections hastens the cure, and this is not incompatible with the fact that such diseases do get well without atropine, with and without other treatment; and also that corneal ulcers may exist for a very long time without iritis, even when atropine is not used. For those velvety conjunctivæ there is not any remedy equal to cleanliness and nitrate of silver, and it does not matter what the origin of the affection may have been.

I use nitrate of silver always with boric acid, sometimes with glycerin and alcohol also. I do not use strong solutions ever, and think them contraindicated always. For trachoma, with or without expression, I use a solution of silver nitrate of one-tenth to one-fifth of a grain as often as in my judgment that particular case may require. The eye is irrigated very freely from six to eight times a day with bichloride (in salt solution), 1:40,000. Before applying the silver solution, and before irrigation, the conjunctival sac should be thoroughly cleansed by wiping with absorbent cotton; the toilet is completed by carefully wiping dry the edges of the lids; this removes moisture and decomposing particles which induce itching, rubbing, and consequent increased inflow of blood.

Illustrating the difference in results as between bluestone and bichloride, I will cite the following two cases:

R., an editor of a country paper, had been treated for trachoma by six or eight men, more or less eminent, both in Germany, whither he had journeyed for relief, and in this country, but with only temporary relief. When I saw him, the face was averted;

the eyelids were shortened, slightly incurved, and the inner surfaces were scarred. There were some fresh corneal ulcers, also old scars. There was lacrymation, with a running nose. In short, there was chronic trachoma. Under the treatment outlined above, he was immediately relieved, and able in three weeks to return to his work, using the bichloride at home; and in three months the eyes were practically well, and have remained so, now twelve years. Some time after the return of R. to his home, he was traveling through an adjoining county when he stopped at the house of Dr. B., who had known him in the days of his trachoma. Dr. B. and his family, four persons, had trachoma; the weather was hot, and they were all as thoroughly miserable as it is possible to be, sweltering in a close room, all of them with ulcers of the cornea. R. shared with Dr. B. his knowledge of a successful treatment of trachoma, and that treatment was instituted at once, with the result that the physician and his family were rapidly made better, and eventually cured. Dr. B. had used the bluestone faithfully for several years, yet it had not been beneficent in its effects.

I could add many cases in which the copper sulphate had been used for a long time with failure, and in which a more rational treatment with weak solutions of silver nitrate and frequent irrigations with bichloride had been followed by immediate and marked betterment, with eventual cure; but a statement of the fact will be as convincing. The most difficult part of the treatment of a trachoma is the finishing, and for this the best remedy is perhaps a solution of tannic acid and boric acid in glycerin and water. When I wish to stimulate the cornea to increased tissue change, I add alcohol. I have not seen staining of the conjunctiva occur from the use of the weak silver solution, even when its application had been kept up for a long time.

I would sum up my conclusions thus:

1. Copper sulphate in ocular affections is maleficent in its effects. 2. Any good effect following the application of the solid copper sulphate in any disease of the eye may be obtained with the use of safer and practically painless means. 3. Trachoma is most successfully treated with weak solutions of silver nitrate, together with frequent irrigation with weak bichloride solution in normal salt. 4. No application to an inflamed conjunctiva which produces a lasting pain should be countenanced. 5. Expression is not absolutely essential, yet much hastens the cure of trachoma. 6. A mydriatic should be used in every disease of the eye involving corneal lesions. 7. Copper has ruined more eyes than it has ever benefited.

145 West Fifth Street.

Differential Diagnosis of Smallpox from Other Diseases.—J. Coffman calls attention to the mild type of smallpox now so prevalent in several American cities. It is often mistaken for impetigo contagiosa, but in the latter disease there are no prodromal symptoms, and a watery vesicle forms which soon bursts and forms a scab. In cerebrospinal meningitis we have the opisthotonos; the face is pale, instead of flushed, as in smallpox, and no remission of symptoms occurs on the appearance of eruption. The eruption consists of erythema, echymosis, etc., which is not regular in appearance. In typhus fever there is the history of exposure as a guide. In scarlet fever and measles the rash comes on in four and ten days, respectively, after exposure, instead of fourteen days, as in smallpox. In measles and scarlet fever the rash fades under pressure of the finger. In measles there is a marked bronchial involvement, with coryza and hypersecretion of tears. The temperature and other symptoms continue even after the advent of the rash. In scarlet fever there is a very rapid pulse; in smallpox the pulse is full and slow. The skin either peels off, or, as in measles, desquamates in fine bran-like particles. In smallpox scabbing occurs. The one disease with which smallpox has been confounded the most frequently in this mild epidemic in this country is chicken-pox. It has been remarked by some that chicken-pox does not occur in adults. This is true in a measure, yet cases do occur in young adults. The exanthem of smallpox first appears in the form of papules, developing in regular order on the third day, appearing first on the face, about the border of the hair, on the hands and wrists, then on other parts of the body. Their appearance is preceded by an initial stage of forty-eight hours, which is characterized by an elevated temperature; when the rash or papules appear, the temperature drops to normal, and other symptoms subside so much that patients wish to go back to their usual occupation, and sometimes do so, thinking that there is little the matter with them. The papules involve the entire skin, and are firm, with a shot-like feel. They cannot be broken by pressure of the finger nail. The eruption requires ten to twelve days or more to pass through its various stages; in even extremely mild cases, it requires at least six days; when the crusts form and drop off, a pigmented scar is left, which is apt to be pitted.—*Pennsylvania Medical Journal.*

Pessimism in Cancer.—G. Wiley Broome protests against the pessimistic attitude of certain physicians in regard to ascertaining the cause of cancer. He believes that in time it will be proved to be of parasitic origin. The distinctive character of malignant tumors in the rapidity of their development, the extension of metastases, which so strongly resemble those of diseases known to be due to bacteria, the cachexia out of proportion to the extent of the local disease, and suggesting the formation of a toxic substance, the fact that a spontaneous cure never takes place, the disease moving onward relentlessly to the fatal issue, and finally the liability of recurrence even after operation, are so many clinical evidences pointing to a parasitic origin. Laboratory researches are not yet conclusive, but point to this origin. Plimmer examined microscopically 1,298 cases of carcinoma, in 1,130 of which he found parasitic organisms, while ninety of the entire number were unfit for examination. He states positively that those bodies are constantly present in cancer and constantly absent in other diseases or degenerative conditions. The author believes the outlook to be very hopeful as regards the discovery of the cause and the cure of cancer.—*St. Louis Medical Review.*

Hepatic Inadequacy and Its Relation to Irregular Gout, with Special Reference to Treatment.—J. Burney Yeo says that in the cases which we are accustomed to recognize as cases of "irregular gout," the clinical evidence seems to point to hepatic inadequacy as being the initial cause of these morbid states. He has great doubts whether uric acid has any other relation to gout than that its overproduction in the human body is a result of the "gouty" state. He upholds the use of the much-decried calomel, and believes in the beneficial action of the sodium salts. The symptoms of irregular gout referable to hepatic inadequacy are pale faces, occasional enlargement of the liver, muddy complexion, yellowish conjunctiva, a sweetish-bitter taste, loss of appetite, and often a high-colored urine of high specific gravity. The glycogenic function, the function of metabolism of nitrogenous material, and that of bile formation, are all disturbed in the gouty. The author says that a simple diet is the best, but that individual cases must be studied in prescribing diet. His chief aim in this article is to defend the sodium salts, as he believes them to be the most valuable and indispensable of hepatic stimulants.—*The Therapeutic Gazette.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 Fifth Avenue

New York, September 21, 1901

THE REVELATIONS OF THE AUTOPSY.

THE revelations of the autopsy on the body of President McKinley are deeply significant from many pathological and surgical points. While the report of the physicians is meant to be merely a preliminary one, the main facts thus far presented are sufficiently explicit to anticipate in all essential particulars the fuller account which is promised later.

Taken in connection with the clinical history of the case, and the extremely optimistic views of some of the consultants, the discovery of certain of the lesions named is both a surprise and a disappointment. It is a pity indeed that such an evident failure in diagnosis should have been so conspicuously demonstrated to the general public. It has proved, in fact, the lost opportunity for an entirely contrary exhibition of judgment, skill, and tact.

In reconciling the findings after death with the symptoms during life, there are many relations between causes and effects, which, although hidden before, are now very painfully apparent. We may comfort ourselves by saying that, under the circumstances, events were uncontrollable and results unavoidable, but the public, alas! view the real situation in a very matter-of-fact way.

The operation of suturing the stomach wounds was timely, proper, and, so far as it went, brilliant. Medical men the world over were proud to hear that it had been done so promptly and so well upon a person of such importance.

But now, in the light of the autopsy, we know that the operation, carefully conducted as it was, was necessarily an incomplete one. This is speaking of the procedure from a strictly surgical standpoint, irrespective of the ultimate doom of the patient in any event. Time was precious, and prolonged search for the ball was impossible, consequently the condition and course of the wound beyond the stomach could not be positively ascertained at the time. The surgeons satisfied themselves, therefore, that it was safe to leave this terminal wound to itself and close up the abdomen. They used their best judgment under trying conditions; but unfortunately, that judgment was in error.

Then came the bulletins and interviews so eagerly read by an anxious nation. It was stated at first that the stomach wounds were the only causes for anxiety, that the ball having lodged in the muscles of the back would become safely encysted, and that septic peritonitis from possible leakage of the stomach contents was the only thing to be feared. When the latter danger was over, there came the surprising intelligence that the patient would certainly recover. This in face of a continued high temperature and rapid pulse! Then it was announced that all the wounds had healed perfectly, and the only real danger was centered in a weak heart. Hardly had this bulletin been issued when it was announced that the external wound was found to be infected, necessitating the removal of some stitches. Still it was said that the distinguished patient was doing excellently well—in fact, even better than before. Next was the report of an attack of indigestion, claimed to be due to food given too soon, and last of all and without warning came the appalling accounts of his rapid collapse and surprisingly quick death.

Worst of all, however, were the actual facts of the autopsy which seemed to prove to the public that the doctors had been wrong in their conception of the case from the beginning to the end.

Sadly enough, not one of the principal lesions gave any evidence of its existence during life. The good condition of the wound behind the stomach, of which all the surgeons were so pronouncedly confident, was an illusion and a snare. What was considered to be a most insignificant factor became the most important of all. Instead of the terminal track of the bullet being healed and the ball encysted, it was found, at the autopsy, to be gangrenous throughout. Thus a most startling error of diagnosis was flauntingly accentuated by an indignant and astonished press.

The practical surgeon very properly asks himself why the condition and the direction of the track behind the stomach was not discovered at the time the parts were exposed during the operation? That the problem was not solved then and there was certainly not due to any want of forethought on the part of the operator, whose skill in his line no one can question. The only answer must be that such a thorough examination of the parts was impossible at the time. Still it seems hard to explain why all the gentlemen on the case were so satisfied with the real nature of a wound that they, obviously, knew nothing about.

The MEDICAL RECORD was exceedingly anxious on this point and earnestly called attention to the possibility of there being a wound of the pancreas or kidney or both. Unfortunately, as the sequel too well shows, we were right in at least one particular.

Another matter is that which referred to the desirability of an *x*-ray examination to locate the ball. The RECORD urged this as of the greatest importance, and yet, with the apparatus at hand, it was repeatedly and publicly stated that such an examination was not at all necessary. In fact, it seemed safer to guess than to be sure. What comment suggests itself in this connection when even at the autopsy, so far as can be ascertained at present, it was not considered worth the trouble to search for the ball beyond a certain point! What excuse must be offered to the public for the utter inability to find the bullet even in the dead body! All these matters may, however, be properly explained when the fuller account of the post mortem is given to the medical and lay public.

Many different theories have been offered by the medical attendants concerning the cause of gangrene of the bullet track. By some the condition is charged to a poisoned bullet, by others to the leakage of pancreatic juice into the bullet sinus, and

by still others to mere lack of recuperative energy in the tissues involved.

On these points, however, the profession is willing to suspend judgment, pending the completion and publication of the official reports of the post-mortem examiners.

Viewing the strictly surgical aspects of the case in the light of the autopsical demonstrations, certain points of treatment might naturally suggest themselves. Everyone knows that such an injury as existed in the President's case is uniformly fatal. The most favorable result that could have been expected was the healing of the wound and the possible establishment of a fistula. This would certainly be infinitely better even as a tentative measure than accidentally leaving a leaking kidney or pancreas in a closed cavity to work such mischief as was manifested in the gangrenous condition of the surrounding tissues of the case in question.

Allowing that the bullet had actually lodged in the muscles of the back, also that the missile was within easy reach, it would be following a good surgical rule to establish drainage by the most direct route posteriorly. This course, however, could not be followed, as the bullet, on account of the unfortunate conditions already noted, was not accurately located. Under the circumstances, therefore, and taking everything into consideration, it is comforting to note that all was done for the distinguished patient that was possible. In fact, as was repeatedly stated by the operator, "the case was a fatal one from the start."

In thus remarking upon the public aspects of the case it is only for the purpose of getting at the truth and learning perhaps a useful lesson. In the same spirit we can afford to view the strictly professional side. To err is human, but wisdom comes from experience. It is safe to say that under like circumstances in future the gentlemen concerned would act somewhat differently. We sincerely trust that they at least would not then be asked to explain why they allowed a lost ball to be buried with the victim's body.

BONE AND IVORY FASTENERS IN THE TREATMENT OF FRACTURES.

SURGEONS have, during the past few years, experimented with a number of appliances made of different substances, in their efforts to find the best material for maintaining apposition of the fragments of a broken bone. Two kinds of material have been used, absorbable and non-absorbable, of which the latter has the advantages of cheapness and strength, but also the more than counterbalancing disadvantage expressed by the adjective non-absorbable. Of absorbable materials, practically only two need be considered—bone and ivory—both these substances having been used in a variety of forms such as collars, nails, and splints. Numbers of good results have been reported by different observers. The preparation of a bone or ivory collar or nail is not a difficult matter, nor is its sterilization; and it may be further noted that the tibia and the femur of the ox lend themselves very satisfactorily to the formation of such objects.

The most important points in this subject are the class of cases suitable and the results obtained compared with the results of other methods. It is clear that there is a large class of fractures to which open operative measures will never have to be applied, but there are still many cases in which it is difficult or impossible to obtain reduction without direct access to the site of fracture, and to maintain it without some mechanical aid applied directly to the fragments. Some fractures of the femur belong in this class, especially when there is much obliquity of the line of fracture, and indeed we may encounter the same difficulty in any of the long bones, if only the break is oblique enough. We may, therefore, say that, in cases in which ordinary means of reduction fail, we must consider the advisability of making an incision and thus reaching the seat of the difficulty. In compound fractures it will apparently often be advisable to undertake to fasten the fragments with bone or ivory plates or nails, since such measures seem to assist in preventing failure to unite, and the formation of a pseudarthrosis, unfortunately common enough after compound fractures. The general rule may therefore be laid down that in fractures, either simple or compound, when reduction is impossible by ordinary means, we must consider the application of bone or ivory supports in the shape of collars, nails, or screws to maintain the ends of the bones in proper relation.

In considering the results after such procedures, we must make allowances for the kind of fracture and also apparently for the material used, in which connection we may say that the day of non-absorbable material is probably past. In a number of instances an ivory plug has been inserted into the medullary cavity of a long bone at the point of fracture, and the broken ends thus supported. There is no necessity for introducing such a large mass of ivory into the tissues, and so taxing their powers of absorption unnecessarily. A perforated hollow cylinder serves the purpose much better and is comparatively easily absorbed. It may be remembered that the ivory or bone appliance needs only strength enough to support the bone; the dressing supports the rest of the limb. Ivory or bone nails or screws, in suitable cases, are probably the best forms to employ, and it will, as a rule, not often be necessary to make use of the larger collar or intramedullary cylinder. In a number of instances in which suppuration has occurred and ivory nails have come out after a number of weeks, these have been found to be eroded to a remarkable degree. This condition was at first attributed to the corroding action of pus, but this view is erroneous. The corrosions represent the efforts of nature to absorb the offending foreign material, and if too much is not required of natural processes the whole object can be removed in the same way. The introduction of these appliances represents an advance in the treatment of certain of the more difficult fractures, and with proper precautions there is no danger in their use. We should say that, as a rule, it would be better to make the collars, plates, and similar articles from the bones of the ox, and the nails and screws from ivory, and it might be added that all these things should be as small as is consistent with safety. Another fact which may be mentioned is that the driving of nails into living bone causes an increase in its growth, a fact which has proved useful in the treatment of some refractory cases of delayed union.

THE SPEED AND CONTROL OF MOTOR-CARS.

The Lancet makes some common-sense comments on the above subject which might be taken to heart and acted upon by the chauffeurs of motor vehicles in New York City, and especially by those of horseless ambulances. The writer delivers himself in the following words:

"The series of accidents which have occurred in this country and in other countries during the past week is calculated to bring the motor-car into disrepute, and we counsel all interested in any way in motor-cars to do their utmost to suppress furious driving. All motor-car drivers should remember that motor-cars cannot be let loose on streets like so many railway trains. Present arrangements will not permit of it. Until motor-cars have a track of their own they must be placed under the strictest possible control in regard to speed and the rule of the road. With motor-cars coming round sharp corners at high speed, pedestrians need almost a new sense. The 'pip, pip,' is, as a rule, under these circumstances, not a timely warning, and people are likely to be run over before even they can realize that a motor-car is turning the corner. It would be well enough if it were possible that certain tracks in our busy thoroughfares could be allotted to the motor-car, but that is not possible and therefore, in the interests of the safety of the public, this method of traveling must be kept within bounds. The temptation to attain a high speed is, we fear, very strong when a driver knows that he is in possession of potentialities which neither overstrain nor exhaust his 'petrol steed.' It is difficult to enforce one set of rules for the country and another set for the high streets of the towns, but, as we have said, such rules are necessary in order to protect the public. It canot be gainsaid that the motor-car is by many people viewed with terror and alarm, inspired through the fault of drivers themselves. The latter forget that a series of a hundred explosions in order to gain motion is a new feature on the road, as is also the rate of speed at which the motor-car is able to travel. We do not doubt that in due time the noise will be got rid of, but that achievement may likely enough prove a new danger. The temptation to increase speed will be greater than ever. We could wish for some invention by means of which the speed of a motor-car could be automatically kept within legal bounds. Surely, in these days of extraordinary engineering skill, it would be possible to devise an arrangement attached to the axle of the motor-car which would check the speed of a car as soon as it rose to a certain and dangerous point. The attachment of such an arrangement to a motor-car could be made compulsory, and anyone found without such a method of control could be fined. We have no wish to interfere with any advance in means of locomotion, but this advance must not be made at the expense of the public safety."

The *Spectator* has also an article on the same subject and after discussing the manifold difficulties in the way of compelling the chauffeurs of automobiles to have some regard for the safety of those who travel on the roads or streets, either upon the instruments provided them by nature or drawn by horse-power, and submits that the only effective methods of restraining the ardor of the strenuous chauffeurs is to provide that no car capable of high speed should be allowed to use the roads except when in charge of a driver who holds a certificate that he is competent to manage and drive the machine. Assuredly, in the streets of a crowded town, the driving of automobiles by unskilled persons is a distinct menace to the life and limbs of all those who use other methods of locomotion, and should be strictly forbidden. But even such a measure will not be sufficient to ensure the safety of the general public. Many skilled drivers, reckless of their own necks and careless of other people's bodies and nerves, travel through the busy streets of large cities at a dangerous rate of speed. This example, too, is frequently set by individuals who should know better. There have been instances recently in Newport and elsewhere in which prominent persons have wilfully disregarded regulations with regard to speed, and have in consequence been a source of grave danger to the community at large. Again, the chauffeurs of hospital ambulances, although it is necessary for them to arrive at their destination as quickly as possible, have no right to lay aside every precaution, and particularly is the custom of racing to be most strongly condemned.

THE PATHOLOGY OF GASTRIC TETANY.

TETANY is a spasmodic disorder of varied—probably toxic—origin, which prevails especially in certain parts of the world, Vienna and at times particularly in the spring. It has frequently been observed in connection with dilatation of the stomach, and it is not unreasonably believed under such circumstances to be dependent upon the toxic products of morbid digestive activity. Little is known concerning the identity or the nature of these poisonous substances, so that the results of a study of the gastric contents from a case of tetany with dilatation of the stomach as reported by Drs. W. B. Haliburton and John F. McKendrick (*British Medical Journal*, June 29, 1901) should prove to be not without interest. The patient in the case reported was a middle-aged man in whom pyloric obstruction had developed as a result of cicatrization of a gastric ulcer, and a stomach-tube had been used two or three times a day for three years. Following a severe tetanoid seizure, experimental observations of the gastric contents were made, which disclosed the presence of a toxic substance that, when injected into an animal, produced a marked fall of blood-pressure and slowing of the heart-beat. This substance was not present in the normal gastric contents of health and moreover, after neutralization of the tetany fluid practically no fall of pressure was obtained. The substance was soluble in alcohol and in normal saline solution and its injection into animals failed to cause either direct or reflex excitation of the cardio-inhibitory centers so that it seems not improbable that other centers in the brain or cord are similarly excited. Subsequently to the attacks noted, some operation on the stomach, probably either pyloroplasty or gastro-enterostomy, but whose exact nature is not stated, was performed, and the patient had no subsequent return of the symptoms.

The Medical Club of Philadelphia.—At the next meeting of this association on Thursday, September 26, a reception will be given to the president and members of the Medical Society of the State of Pennsylvania.

News of the Week.

Harmony Among the President's Surgeons.—One of the sensational papers in this city has been endeavoring to make out that continual bickerings disgraced the surgeons who were in attendance upon President McKinley. The charges, receiving at first no notice from the victims of the journal's mendacity, became finally so malignant that the gentlemen attacked were forced to make a formal denial, and have issued the following statement: "The undersigned, surgeons and physicians, who were in attendance on the late President McKinley, have had their attention called to certain sensational statements recently published in the daily papers, and particularly in one New York paper, indicating dissention and mutual recrimination among them. We desire to say to the press and the public, once for all, that every such publication and alleged interview with any of us containing criticism of one another or of any of our associates, is false and is nothing but scandal mongering. We say again that there was never a serious disagreement among the professional attendants as to any of the symptoms or as to treatment of the case, or as to bulletins which were issued. A very unusual harmony of opinion and of action prevailed all through the case. The unfortunate result could not have been foreseen before the unfavorable symptoms declared themselves late on the sixth day, and could not have been prevented by any human agency. Pending the completion and publication of the official reports of the post-mortem examiners and of the attending staff, we shall refuse to make any further statements for publication, and alleged interviews with any of us may be known to be fictitious. (Signed). Matthew D. Mann, Roswell Park, Herman Mynter, Eugene Wasdin, Charles G. Stockton."

Damages Claimed by a Smallpox Nurse.—A woman in Manasquan, N. J., has brought suit for $10,000 damages against two physicians of that place. A woman and her daughter were taken ill last June and the plaintiff in the suit was engaged as nurse, taking the position under the assurance, she claims, of the two physicians that there was no danger from the disease with which the patients were suffering. They had smallpox and the nurse contracted it later, and as soon as possible after her recovery instituted suit against the doctors.

Arrest of a Physician in Connection with the Murder of the President.—The papers a few days ago announced the arrest of Dr. I. Saylin, a Buffalo physician, apparently on suspicion of complicity in some anarchistic plot. It was alleged that he and Emma Goldman and others met in Buffalo to arrange the details of the plot to assassinate President McKinley. He says that the meeting was purely social, and the Goldman woman denies that it took place at all. After a short detention Dr. Saylin was released, there being no evidence against him.

The New York State Veterinary Association held its eleventh annual meeting at Cornell University, Ithaca, on September 10 and 11, over one hundred veterinarians being in attendance. A rather heated discussion was aroused by a motion for the expulsion from the society of Dr. Claude Morris of Binghamton, who was charged with conduct unbecoming a member of the organization on account of a letter he wrote to the Secretary of War last spring, strongly condemning the Veterinary Army bill. This measure provided for the grading of the veterinarians in the army. It was argued at the meeting that Dr. Morris's expulsion from the American Veterinary Association at its recent meeting in Atlantic City warranted the State society in taking immediate steps. Opposition to the motion prevailed, and it was decided to give Dr. Morris one year's time to prepare a defence. Officers of the society for the next year were elected as follows: *President*, Prof. James Law, Dean of the Cornell Veterinary faculty; *Vice-President*, Prof. James Robertson of New York City; *Secretary* and *Treasurer*, W. H. Kelly of Albany; *Censors*, Charles Cowal of Ogdensburg, E. B. Ackerman of New York City, Harry Sutterby of Batavia, E. B. Ingalls of Mohawk, and H. D. Gill of New York City. The next meeting of the association will be held in Brooklyn.

The Autopsy on the Body of President McKinley was made about noon on Saturday, nine hours after death. It was performed by Dr. Harvey D. Gaylord, pathologist of the New York State Laboratory, assisted by Dr. Herman G. Metzinger, also of the State Laboratory, in the presence of the attending physicians and surgeons. These included Drs. Charles McBurney and Edward G. Janeway of New York, W. P. Kendall, Surgeon, U. S. A., Edward L. Munson, Assistant Surgeon, U. S. A., W. W. Johnson, Charles Cary, and Hermanus L. Baer. District Attorney Penney was also present in his official capacity. The official report of the autopsy, issued about five o'clock, read as follows:

"The bullet which struck over the breastbone did not pass through the skin and did little harm. The other bullet passed through both walls of the stomach near its lower border. Both holes were found to be perfectly closed by the stitches, but the tissue around each hole had become gangrenous. After passing the stomach, the bullet passed into the back walls of the abdomen, hitting and tearing the upper end of the kidney. This portion of the bullet track was also gangrenous, the gangrene involving the pancreas. The bullet has not yet been found. There was no sign of peritonitis or disease of other organs. The heart walls were very thin. There was no evidence of any attempt to repair by nature, and death resulted from the gangrene, which affected the stomach around the bullet wounds, as well as the tissues around the further course of the bullet. Death was unavoidable by any surgical or medical treatment, and was the direct result of the bullet wound.

"Harvey D. Gaylord, M.D.,
"Herman G. Matzinger, M.D.
"P. H. Rixey, M.D.,
"Matthew D. Mann, M.D.,
"Herman Mynter, M.D.,
"Roswell Park, M.D.,
"Eugene Wasdin, M.D.,
"Charles M. Stockton, M.D.,
"Edward G. Janeway, M.D.
"W. W. Johnson, M.D.,
"W. P. Kendall, Surgeon, U. S. Army
"Charles Cary, M.D.,
"E. L. Munson, Assistant Surgeon, U. S. A.,
"Hermanus L. Baer, M.D."

Dr. McBurney did not sign the report, having been obliged to leave before the autopsy was completed.

Closing of the Sterilized-Milk Booths.—The summer depots of the Nathan Straus sterilized-milk charity closed this week. A greater quantity of milk has been disposed this season than ever before in the ten years that the work has been going on. During the summer nearly 800,000 bottles of milk were distributed and over a million glasses were drank in the different booths. During the winter only four depots will remain open.

In Honor of Dr. N. S. Davis.—Under the auspices of the Chicago Medical Society a banquet and celebration have been organized in honor of Nathan Smith Davis, M.D., LL.D., who is the oldest living President of the society, and widely known and honored among the profession by his long connec-

tion with the American Medical Association and other medical societies. The banquet will take place at the Auditorium Hotel, Chicago, on Saturday evening, October 5, 1901. The committee in charge of the celebration consists of Drs. Christian Fenger, Jas. H. Stowell, W. S. Haines, F. X. Walls, E. F. Wells, and Arthur R. Edwards.

Dr. Gustav G. Fischlowitz has been appointed assistant attending surgeon to the New York Maternity Hospital.

The British Medical Association.—The announcement is made that the next annual meeting of the British Medical Association will be held in Manchester. The last visit there of the association was about twenty-five years ago. The President-elect is Mr. Walter Whitehead, professor of clinical surgery at Victoria University.

Medical Society of the State of New York.—The first of the semi-annual meetings of this society will be held in New York City, in the Academy of Medicine, on Tuesday and Wednesday, October 15 and 16, 1901. The sessions will be from 9.30 A.M. to 1 P.M. and from 2.30 to 6 P.M. each day, and an evening session will be held on Tuesday at 8 P.M. On Wednesday evening at 8 o'clock there will be a reception tendered the members and their guests. The program is a very rich one, containing sixty-four titles. On Tuesday evening there will be a special discussion on "Some of the Diseases of the Liver and Bile Passages." A large attendance is anticipated.

Hall Caine's Absurdities.—One would think when a novelist had once been convicted of gross ignorance on medical matter concerning which he wrote with glibness, he would not make a second incursion in that dangerous field unless he was fairly sure of his ground. Not so Mr. Hall Caine (though perhaps we err in dignifying him with the title of novelist). In his latest effort, "The Eternal City," he describes how a medical man examined the breast of a patient and the glands under her arms, and, finding cancer, announced that a nurse must be summoned immediately. This practitioner, who is supposed to be the most fashionable doctor in Rome, tells the friends a few pages further along in the dreary tale that if the cancer had been diagnosed earlier "nephrectomy" might have been possible, but that the case as he found it was beyond the reach of surgery.

Prof. Van Gehuchten has received from the Belgian Government an award of five thousand francs for his original work on the central nervous system.

Charges against a Coroner's Physician.—Formal charges were filed against Dr. Hamilton Williams, Coroner's physician to Coroner Zucca, at a recent meeting of the Board of Coroners. It is alleged that he has been dilatory in attending Coroner's cases and that he was discourteous in the performance of his duty. The charges allege "improper conduct, incompetency, and unfitness further to fill the position of Coroner's physician," and further charge neglect of duty as such Coroner's physician. There are several specifications in the complaint, which charges that, while attending hospitals, Dr. Williams was discourteous in his bearing toward officials and employes, and particularly toward medical students, who were anxious to be present at autopsies. Another charge recites that he was "dilatory, discourteous, rude, and brusque" in several specific cases of autopsy on persons who had died in hospital. By this conduct it is charged he caused grief and annoyance to the relatives and friends of persons he had attended officially, and that whenever the deceased person carried life insurance he uniformly refused to give a certificate of death without payment of a fee varying from five to fifteen dollars. Dr. Williams denies the truth of one and all these charges, and says that it is nothing but an attempt on the part of his political enemies to secure his dismissal.

An International Congress of Clinical Anthropology was in session last week in Amsterdam. Among the vice-presidents elected were Dr. Henry Havelock Ellis of England and Mr. Clark Bell of New York City.

A Physician's Carrier Pigeon Service.—A correspondent of the *New York Times* says that Dr. E. W. Gould of Rockland probably has the most novel messenger service in Maine. The doctor makes a specialty of homing pigeons. The other day he was called to Matinicus Island to attend a patient whose condition was very serious. To reach there he had to make a dangerous trip over twenty miles of rock-strewn, storm-tossed waters. Before he left the island he gave into the keeping of the family of the patient six homing pigeons, to be used as messengers to inform him of the patient's condition. The messages came faithfully and regularly and brought assurance to the physician of his patient's steady progress toward recovery.

Philadelphia County Medical Society.—At a stated meeting held September 11, Dr. EMMA E. MUSSON read a paper entitled "Rarefying Ostitis in Chronic Purulent Ethmoiditis Simulating Atrophic Rhinitis," and Dr. BOARDMAN REED a paper entitled "The Etiology and Symptomatology of Constipation in Deciding the Differential Diagnosis Between Atonic and Spastic Constipation."

The Pathological Society of Philadelphia.—At a stated meeting held September 12th, Dr. J. D. STEELE exhibited a "Fibroid Pancreas from a Case of Diabetes," and nominations of officers were made for the ensuing year.

Obituary Notes.—Dr. GEORGE W. DELAP of Brooklyn died last week at his home in that borough at the age of forty-five years. He was a graduate of the Long Island College Hospital Medical School in the class of 1885. At the time of his death he was resting under a charge of extortion preferred against him by a woman who alleged that she was compelled to pay him a sum of money to secure a verdict of accidental death in the case of her husband, so that she might be able to secure the insurance. Other charges of the same character were pending against him.

Dr. THEODORE Z. SMITH, of Westfield, N. J., died on September 12, at his home in that place. He was born in Williamsburg, Brooklyn, forty-nine years ago, and was graduated from the College of Physicians and Surgeons in New York City in 1878.

Dr. LOUIS WARFIELD RITCHIE, of Georgetown, D. C., died of Bright's disease on September 9. He was fifty-eight years old and was the son of Dr. Joshua Ritchie, a lifelong practitioner of Georgetown and an instructor in Georgetown College. Dr. Ritchie was in the medical department of the army during the Civil War and performed notable service at Antietam and on other fields. He was a graduate of the Medical Department of the University of Georgetown in the class of 1863.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PUBLIC HEALTH—OUTBREAK OF SMALLPOX IN LONDON—SIR J. CRICHTON-BROWNE'S ADDRESS TO SANITARY INSPECTORS—ARSENIC AND BERIBERI—RUNNING AMOK—TRISMUS—DR. ORD ON HEALTH OF CIVIL SERVICE CANDIDATES—MILK DIET—A COLONEL DEFENDS QUACKERY—BROMPTON HOSPITAL—THE CHIGOE.

LONDON, August 30, 1901.

THE mortality returns are on the whole favorable, but there are some exceptions. The deaths last week in the thirty-three great towns corresponded to an annual rate of 21.6 per 1,000 of their aggregate population. In the previous three weeks the rate had been 22.4, 22.1, and 21.3. In London the rates for the four weeks were 20.0, 18.8, 19.6 and 19.2. During the four weeks ending last Saturday the rate averaged 19.4, which is 1.0 per 1,000 below the mean rate in the corresponding periods of the decade, 1891-1900. These figures are for deaths registered, and must be considered in that respect only. It is obvious that cases might begin in those periods and be fatal later, and if deaths only are taken into account an outbreak of zymotic disease would not at first attract attention.

An instance of this is seen in the fact that no death from smallpox was registered in the period above referred to, but cases had occurred in London, and at this moment there is a threatening outbreak on the increase. The returns from the Metropolitan Asylums Board, and the Fever Hospitals show that on Saturday there were 41 cases under treatment. The admissions in the four weeks named were 4, 3, 8, and 30, showing a rapid increase. On Saturday there were 7 fresh admissions, on Sunday, 6; on Monday, 15, and 30 more by Thursday. By yesterday the number of cases under treatment had reached 70.

The outbreak has thus practically developed during the week. It is confined mostly to the northwestern district of the metropolis, though cases have occurred in some other parts. Great efforts are being made to prevent the spread of the disease by hunting up the cases and carefully disinfecting the dwellings they had occupied. We are so unaccustomed to meet with smallpox in London that there are many practitioners who have never seen a case, and are perhaps at a loss to diagnose it at first. The Asylums Board have arranged for the practitioner in any suspected case to telegraph to the office, when a message is sent to the nearest ambulance station, whence a special wagon with a nurse goes and takes the patient to the central receiving station. There he is examined by Dr. Ricketts, and if he considers it to be smallpox the patient is at once conveyed on board the floating hospitals, which are stationed in the most desolate place on the Thames. This plan has worked well in ordinary times and will, no doubt, should an epidemic be established, prove a valuable protection to both the patients and the public.

The Asylums Board was established towards the close of the sixties, and at that time smallpox was much more prevalent. In 1871-1872 there was an epidemic, and the hospitals of the Board had to provide for 16,000 cases. Then there was a falling off. In 1876 there were 2,134 admissions, in 1877, 6,516; in 1878, 4,558; in 1879 the number fell to 1,628. In 1880, there was a rise to 1,082, and the next year a jump to 8,551. The next year they fell again to 1,780, and this fall continued for two years. Our last epidemic was in 1884-5, when the cases numbered 6,363 and 6,104 respectively. Since then we have been pretty free from it. In 1898, there were only 5 admissions; in 1899, there were 82, and in 1900 there were 60.

Yesterday, a conference of the Sanitary Inspectors' Association was held, at which Sir James Crichton-Browne delivered an address. He said that Dr. Koch was the greatest of living bacteriologists, but even his authority could not secure the acceptance of a new doctrine without question. In fact, the sound Harveian doctrine barely passed away when Lord Lister uttered a protest; and since then the tide of opposition has been rising. Science knows no papal infallibility. He thought this great master was premature in his announcement and unfortunate in his choice of an occasion for making it, that the experiments on which he relied were too few and too equivocal to warrant his conclusions, and that he had ignored a mass of observations and experiments which must negative those conclusions, or be proved to be incorrect. Should it be shown, which it has not yet been, that human tuberculosis is not transmitted to other animals, the converse would by no means follow. The suggestion had already proved deplorable, by raising doubts and revolt against existing precautions. The grim ghost raised by Dr. Koch could only be laid by a government inquiry, and there could be little doubt that Mr. Walter Long, who had stamped out rabies, would not be slow to grasp the situation respecting tuberculosis. Dr. Koch had discredited the report of the last Royal Commission, which had up to this time been regarded as a standard authority, and it seemed most desirable that that report should either be confirmed or pronounced obsolete. Meantime prudence dictated that sanitary inspectors should look at things exactly as before Dr. Koch spoke.

The Association unanimously adopted a resolution calling for a government inquiry. Papers were submitted to the conference by Sir Alexander Binnie on London main drainage, and by Professor Frank Clowes on the Experimental Treatment of Sewage in London.

You will observe that since the Sanitary Inspectors formed their association, the recognition of eminent men has not been wanting. Its influence is extending, the report showing an increase in adhesions.

Arsenical beer and beriberi were mentioned at more than one section at Cheltenham. Thus Mr. Wanklyn commented on the protean powers of combination possessed by arsenic, and said that many failures to find the poison in beer during the late outbreak were the result of not employing Marsh's original test. Though two grains in the shape of arsenious acid is a fatal dose, as much as fifteen grains has been taken in the form of cacodylic acid, or its soda salt, without ill effect. In the address read for Major Ross the resemblance between beriberi and arsenical beer poisoning was mentioned, and Mr. Cantlie suggested that the opinion of those who had seen beriberi in the East would be acceptable. Dr. Manson admitted a difficulty in distinguishing a case of beriberi from alcoholic neuritis, when the patient with the latter disease came from a country where the former prevailed. He thought we should persistently seek for some definite clinical sign that might clear up the diagnosis. Dr. Henderson said he had seen many cases of beriberi in China, but could not remember pigmentation of the skin occurring in any one of them. He, therefore, held it need not be confused with chronic arsenical poisoning. He rejected the suggestion of metallic poisoning being the cause of beriberi. Dr. Max Simon said there was nothing in common between beriberi and metallic poisoning, arsenic or other, except neuritis. In beriberi there were no skin, eye or digestive symptoms present to support the suggestion.

The state of blind, furious, homicidal mania seen among Malays and called "running *amok*" is commonly supposed to be peculiar to that race. But according to Dr. Moffat of Uganda, the Nubians, Soudanese, and other African tribes are addicted to it. They ascribe it to "seeing the devil," and after the fit always declare they have no recollection of their actions while it was on them. He mentioned in the Tropical Section, as a curious fact about nervous diseases among the natives of East Africa, that locomotor ataxia and general paralysis of the insane are both extremely rare, though syphilis is common, as are also sexual excesses and intemperance. Nevertheless, neuroses are not common.

The exciting causes of running *amok* are usually put down to fright, grief, or brooding over wrongs, real or imaginary. But malarial or other severe illness may occasion an attack. The sight of blood is said to have excited it. The question of the legal responsibility of a person seized with a fit of *amok* is rather perplexing. Dr. Ellis is inclined to admit two varieties, one purely pathological, the other more or less feigned. The latter may be suspected when revenge is accomplished in the fit. Dr. Henderson remarked that in Shanghai the Chinese are prone to acute mania and suicidal impulses.

Trismus neonatorum would seem to be endemic in Hong Kong, for Mr. Carthe mentioned at Cheltenham that in his experience there the mortality from this disease was enormous among Chinese infants. Between 1887 and 1896, the deaths from trismus equaled fifty per cent. of the total mortality. He had seen a death in a European child from the disease, the monthly nurse was also European, but had come straight from a convent, where the disease is always rife, and no doubt brought the infection. Dr. Crombie said it was a common disease in Calcutta.

The report of the Civil Service Commissioners has just appeared. Among a mass of information on matters connected with the competitive examinations is an interesting report from Dr. Ord, who, since 1894, has conducted the medical examination of candidates for appointments. They have previously passed their literary examinations, and are to be regarded as selected candidates presenting themselves after a long course of study and the final strain of the competition. At first, Dr. Ord expected to find many more or less weakly after their prolonged mental work, which might well interfere with exercise. He looked for the results of burning midnight oil rather than the development of athletics. But when he came to examine them individually, he found none of them unequal to the requirements of a service calling for strength, activity, and

endurance. There was no indication of physical deterioration, but there was the evidence of vigorous health, the stamp of the university and the public school. In 1890, the average age of these candidates was 22½ years; height, 5 feet, 9 inches; girth, 36⅝ inches; weight, 165.8 pounds. These averages were certainly good, and similar to those of other years, and Dr. Ord was much impressed by them, and he feels satisfied that the physical qualities of those young men who have gone to India and other places to serve their country are such as to give every satisfaction—in fact, he writes "their equipment for the work awaiting them has appeared to me to be, though the word may be strong, complete." He found them, for the most part, well set up, manly specimens of English young men, with good muscular development, and he was particularly struck by their good general nutrition. It is certainly satisfactory to find such a high degree of physical energy and capacity combined with mental ability in the young men to whom so much is to be entrusted on behalf of their country.

The talk about boiled milk still goes on, and bids fair to become a permanent topic of conversation. I find most of those who speak to me about it remain convinced that boiling is of great value in preventing the spread of disease. One eminent physician says all milk is boiled the moment it comes into his house, a statement which shows much confidence in the obedience of his cook. Another I know, who drinks milk freely, always has it served up hot, and he says that the story of its being unpalatable is all nonsense, just as it is in the case of water. Either of them, he maintains, is nicer hot than cold, but must be taken as hot as it can be drunk, and then he dilates on the difference between the meaning of hot and warm. If boiling impairs the nutritive value of milk it must surely be in a very minor degree, for there are thousands of healthy children brought up on this sterilized fluid. So many fever cases pass successfully through the most critical stages on milk diet. When milk forms but a small part of the nutriment consumed, any hypothetical deterioration by boiling is surely of no consequence.

A very learned confrère is an enemy to milk in the diet of fever cases, and indeed in any case of feeble digestion, particularly in young children. In health he himself eschews the various forms of milk diet, but regards it as less injurious when given mixed with other things than alone. In the latter case, it is too apt to form indigestible curds, which have to be rejected by vomiting. The late Sir R. Quain was averse to milk diet in consumptive or other delicate cases. A friend of mine took a case to him which they agreed could not last long, and on parting, Sir Richard said, "Don't stuff the poor fellow with milk." "I never do," replied my friend, when the genial baronet grasped his hand and assured him it was such a rare pleasure to meet a doctor who agreed with him about milk in such cases.

The ignorance of presumably well-educated persons on medical matters and their corresponding readiness to instruct others, is forcibly illustrated by a letter of a colonel which was admitted to the *Times* of the 20th inst. This military gentleman attacks the General Medical Council for having removed from the register notorious quacks and gives his testimony to the value of a nostrum advertised by one of them. If the colonel's military opinions are on a par with his assertions on medical matters, he would be wise to keep them to himself.

Tonsillitis from the Standpoint of the General Practitioner.—A. L. Gray states that the differentiation of acute tonsillitis from diphtheria in the early stages is not always possible without bacteriological examination. The forms of follicular tonsillitis have been found in infancy and old age and in both sexes. There are often patches over the tonsils and adjacent parts which closely resemble those of diphtheria, but which are due to streptococcus infection. Milky-white membranous appearances are sometimes found due to the leptothrix buccalis or the oidium albicans. When ulcers are present, they are often covered with a dirty yellowish or grayish necrotic tissue which may be firmly adherent for several days, resembling the diphtheritic membrane. Whenever there is a possible doubt in a case, bacteriological examination should be made at the earliest possible moment. Gray believes that follicular tonsillitis will be found due to a specific bacterium, and thinks that isolation of the patients should be practised.—*The Virginia Medical Semi-Monthly*

NOTES ON SOME OF THE MEDICAL FEATURES OF THE PAN-AMERICAN EXPOSITION.

THE NAVY MEDICAL EXHIBIT—A MODEL OF THE SICK-BAY—THE FOOD EXHIBIT—PRESERVATIVES AND ADULTERANTS—THE BUREAU OF ANIMAL INDUSTRY—PURE MILK—CALORIMETERS—LIFE INSURANCE STATISTICS—DEPARTMENT OF HYGIENE AND PUBLIC HEALTH—THE CHICAGO AND THE BUFFALO HEALTH DEPARTMENTS—TENEMENT HOUSES—HOSPITALS, ASYLUMS, PUBLIC INSTITUTIONS, AND UNIVERSITIES.

(Special Correspondence of the MEDICAL RECORD.)

THE Navy Medical Department of the United States would appear to be regarded somewhat lightly by those in whose hands the allotting of space for exhibition purposes was placed, as its exhibit, owing, it may be presumed, to lack of room, is meager to a degree, and would convey to a stranger—say a South American—but a poor conception of the resources of the department, and might further give the impression that the naval authorities are by no means keenly solicitous concerning the well-being of their sailors. Such a view, we are convinced, would be a wrong one, as undoubtedly a much more representative display could have been brought together, had not the officials been so unaccountably parsimonious with regard to space.

The seeming indifference to the interests of this great branch of the service is the more curious in the present position of affairs, and at a time when the surgeons of all the navies of the world freely recognize that reforms must be introduced into the system now prevailing of treating the wounded on modern battleships.

At the recent meeting of the British Medical Association, the treatment of the wounded on modern men-of-war was discussed at length, and the opinion was expressed by the prominent surgeons who took part therein that the subject is of predominant importance, and one which must in the near future engage the serious attention of naval surgeons. Fleet Surgeon G. Kirker pointed out that facilities for operating on board battleships and cruisers of the existing type are wofully deficient, and urged that steps be taken at once to remedy the defect. The fact is then plain that there is great and pressing need of better provision for the wounded on modern sea-fighting machines, and the more quickly the public is brought to an appreciation of this necessity the sooner will reforms be brought to pass. Perhaps, however, the authorities wished to provide an object lesson on the shortcomings of the existing methods of caring for the wounded in sea battles, and for this reason were chary in granting an area sufficient for the Navy Medical Department to give an exhibit in keeping with its resources and representing its full means of equipment.

The exhibit at the Buffalo Exposition is in charge of Surgeon S. H. Griffiths, U. S. N., and is a model of a sick-bay with lavatory, dispensary, etc., on a modern battleship. The sick-bay contains four cots, a folding operating table, a wooden chest of drawers, iron washstand, and an oak desk. The bathroom is furnished with a bathtub, shower bath, and water-closet, while in the dispensary are a cupboard, washstand, and litter for transporting wounded on shipboard.

In connection with this latter, it may not be out of place to mention that at the meeting of the British Medical Association, referred to above, Fleet Surgeon Kirker advocated the adoption of a properly devised ambulance sleigh, by which a wounded man could be easily and safely taken down and along all hatchways and passages. It is certain that a device of this description would tend to greatly simplify the whole question of treating the wounded on a modern battleship in an efficient manner, as with the aid of such an apparatus, the position of an operating-room would be a matter of comparatively small moment. It is to be hoped that the general public may be induced to take an interest in the question of the care of the wounded at sea, and by no means can such a result be better obtained than by familiarizing the system in practice on board battleship by illustrating the methods at large expositions. For this reason it is, therefore, a matter of general regret that the exhibit of the Navy Medical Department at the Pan-American Exposition is not more comprehensive.

An annex to the main Government building is devoted to the exhibits gathered together by the Department of Agriculture, among which are those relating to foods, a matter, needless to remark, of scientific interest to the medical profession, and closely affecting the community at large. Dr. Stewart of the Bureau of Animal Industry has charge of this exhibit. Adulteration of food is made a special feature, and the artificial coloring of various articles of diet is excellently illustrated by specimens

treated in this manner arranged in jars. Before proceeding to describe in detail this exhibit, a slight digression, to recapitulate the measures taken in this country to prevent the pernicious custom of adulterating food, may prove instructive.

Legislation against the adulteration of foods in the United States was first made in 1870, and in 1881 three States—New Jersey, New York, and Michigan—passed laws to put a stop to the adulteration of food. Since 1883, a number of States have enacted laws with the same object in view; but national legislation, despite the fact that many bills have been brought before Congress since 1892, has failed utterly to relieve the situation, and food adulterated in one State can be taken to another and sold. Thus legislation up to the present time has been of little or no effect; indeed, more or less of a farce, and will continue to be so until Congress thinks fit to put down adulteration of food with a strong hand.

The many methods of preserving food are given a practical illustration at Buffalo. Food which has undergone such a process is shown in glass receptacles, upon each of which is a label inscribed with a chemical analysis of the article therein contained, as well as the market cost of the materials and the selling price. So significant an exposé of the tricks of the trade should, it would be imagined, open the eyes of the most careless consumers.

Another noteworthy exhibit, typifying the extent to which tampering with food for purposes of profit is carried on, is provided by the display of a number of tubes, containing salicylic acid and other substances used as preservatives, collected from articles of consumption of all kinds. Canned fruits and vegetables are largely represented, from the genuine unsophisticated material to those which, having passed through the hands of the preserver, are sold by the wily retailer to a confiding public as pure.

In the degradation of food—unfortunately so common at the present time—no method is probably more practised than the manufacture of spurious jams and preserves by means of glucose, starch, and coloring matter. This fact is well exemplified at the Pan-American Exposition by an exhibit of strawberry jam, which has been concocted after this receipt, but which is nevertheless foisted upon the innocent housekeeper, probably as home-made.

Wines made from glucose, preserved with salicylic acid, and artificially colored, are also exhibited, and should act as a salutary warning to those of bibulous tendencies.

A cynical philosopher who might chance to stroll through that part of the exhibition given over to foodstuffs could not fail to discover a fund of amusement in the display, and might moralize to his heart's content upon the extraordinary gullibility of the public in allowing itself to be thus cheated. But it must not be forgotten that the subject has also a very serious aspect, and that the remedy lies with this self-same public. If the people at large would only band together, and insist that the Government should step in and take measures prohibiting the sale of adulterated food entirely, and of chemically preserved food to a great extent, the authorities would have no choice but to comply with the demand. Some of the adulterants and many of the preservatives are doubtless comparatively harmless, but this is not altogether the point; a person has the right, when he pays for a certain article of diet, to get that article, and not a noxious compound or an imitation.

In a portion of the building of the Department of Agriculture is the exhibit of the Bureau of Animal Industry, which includes a biological laboratory, "pathological specimens," showing the different phases of diseases common to animals used as human food. An exhibit which is immensely popular, and which draws crowds of interested and curious spectators, is a practical demonstration of the methods practised by the Department of Agriculture at the large packing houses for the detection of trichina and other parasites to which the flesh of the hog is subject. This is effected by microscopical examination, and the mode in which it is carried out is shown by three young women, who make these examinations publicly, and who will, for the satisfaction of visitors, point out specimens of infected meat.

In spite of the much-discussed statement of Koch, that milk procured from a tuberculous animal is not a source of danger to the human race, it will certainly be well—be his theory borne out by further investigations or not—to continue without relaxation our efforts to ensure a supply of uncontaminated milk. The sanitary dairy cans, exhibited by the Department of Agriculture, may be strongly commended to dairy farmers and milk dealers as a means tending to this end. There is also exhibited a series of photographs, illustrating the methods now in use best calculated to prevent the transmission of disease by the agency of milk.

In the center of the building is exhibited a calorimeter used in determining the heat of foods, feeding stuffs, and other materials designed by Professor W. O. Atwater and C. D. Woods, and a respiration calorimeter designed to study the balance of energy, income, and outgo of matter in the animal body, designed by Professor W. O. Atwater and E. B. Rosa.

The exhibits relating to medical matters displayed in the Department of Agriculture are worthy of the close attention both of the scientific man and of the ordinary observer.

The Manufactures and Liberal Arts Building contains several features of special interest to medical men.

The Prudential Life Insurance Company shows a collection of medical statistics bearing upon the influence exerted on the death rate by age, sex, occupation, etc. These statistics are of great value, those dealing with the mortality from tuberculosis perhaps being at the present time of the highest interest. With regard to sex, age, and race, the general conclusions drawn from a consideration of the facts gathered by Frederic L. Hoffman, statistician of the company, are as follows: "That tuberculosis is at the present time the cause of about 200,000 deaths per annum in the United States. The decline which has taken place in the death rate from this cause during the past thirty years has been considerable, but it appears that the male population at ages twenty to sixty has remained almost wholly unaffected, while for the females the decline in the death rate has been considerable at all age periods. The white population is shown to be subject to the disease at a much lower rate than the colored, but for both races there has been a decline in the death rate during the three decades covered by the investigation. Hence the general conclusion and recommendation that efforts toward the prevention of tubercular diseases be especially directed to the male population at ages twenty to sixty, and to the colored population at all age periods."

Several surgical supply firms have a good display of surgical and of other articles pertaining to the surgeon's craft. The manufacturers of artificial limbs are also largely represented.

The exhibits treating of sanitation and hygiene, hospitals, tenement houses, asylums, and public institutions occupy a series of compartments situated at the northeast corner of the building. The department of hygiene and public health is under the charge of Dr. Otto of Buffalo.

In consequence of the limited space assigned to this topic, it was necessary to exclude all solid matter except books and a few articles of a sanitary character which occupy a small space only. The exhibits in this section comprise in general the following materials: Six large maps of the United States, illustrating subjects relating to public health; a series of cards in wing frames, illustrating the vital statistics of certain states and cities, mostly in colored charts and diagrams; photographs, maps, and charts, illustrating the work of several state boards of health; isolation hospitals for infectious diseases; hospitals, homes, and sanatoria for consumptives and crematories. There are also shelves containing reports of national, state, and municipal boards of health, reports of state and local registrars of marriages, births, and deaths; dairy and food commissioners, and sanitary periodicals.

Dr. Arthur B. Reynolds and the members of the Chicago Board of Health have every reason to be proud of the manner in which the mortality rate of that city has been reduced by judicious sanitary measures within the past thirty years. The vital statistics of Chicago exhibited at the Pan-American Exposition affords striking evidence of the efficacy of the means employed. It is stated that since 1872 the average death rate has been reduced by half, and that Chicago, in place of being one of the most notoriously unhealthy cities of the world, can now claim a foremost position in the opposite direction.

Buffalo, too, thanks to the efforts of Dr. Wende and its Board of Health, has at the present time probably the lowest death rate of any large city, not only of this continent, but of the world. The Buffalo Health Department exhibits a chart, illustrating the effect that the use of antitoxin has had in lowering the death rate, photographs of tenement districts of the city, and the advance that has been made in providing the working classes with superior sanitary dwellings, and a chart demonstrating in black and white the good effects upon the general health of the population which have followed the careful carrying out of sanitary reforms. The exhibits in this section are impressive, if only for the fact that they drive home in a convincing way the progress effected in public hygiene in the United States within the past few years.

The tenement house question is rightly dealt with at considerable length in this section of the Exposition. The MEDICAL RECORD has persistently and consistently

advocated the erection of sanitary dwellings for wage earners at a fair rent. As a means of coping with disease, and especially with tuberculosis, Dr Billings and many others have pointed out that no measures can have the success that will result from housing the working inhabitants of large cities in airy, well-ventilated, and sanitary buildings. Vital statistics of London, and large centers of population, both in this country and elsewhere, show that the mortality in the improved dwellings for wage earners is far below the general mortality of these cities the difference being especially marked in infantile mortality.

The exhibit at Buffalo with regard to tenements is worthy of the importance of the subject, and is given by the Tenement House Committee of the Charity Organization Society of the City of New York, providing a practical illustration of what tenement houses should and what they should not be. Three models are displayed in corroboration of this point. The first model is a block of existing tenement houses in the city of New York as it stood on January 1, 1900. This block is bounded by Christie, Forsyth, Canal, and Bayard streets. It includes 39 tenement houses, containing 605 different apartments for 2,781 persons. Of these, 2,315 are over five years of age, and 466 under five years. There are 1,588 rooms and only 264 water closets in the block. There is not one bath in the entire block. Only 40 apartments are supplied with hot water. There are 441 dark rooms, having no ventilation to the outer air, and no light except that derived from other rooms. There are 635 rooms getting their sole light and air from dark and narrow air shafts. During the last five years there have been recorded 32 cases of tuberculosis from this block, and during the past year 13 cases of diphtheria. During the past five years 665 applications for charitable relief have come from this block. The gross rentals derived from the block amount to $113,964 a year. This block is not one of the worst in the city, but merely typical. A second model shows a block of typical tenement houses built in accordance with the laws in force January 1, 1901, showing almost the entire block occupied by these buildings. Each tenement house in this block contains accommodations for four families on each floor, in 14 rooms, making 22 families in each building, and 704 families in the whole block, a total of 4,000 persons in the block. A third model is one of an entire city block of model tenements designed by Ernest Flagg, showing large courts for light and air. Three different groups of improved tenement houses have been built on this plan in New York City. The other portion of the exhibit consists of two winged frames containing photographs illustrating tenement house conditions in America. Photographs are also shown of old, bad tenement houses which have now been destroyed, and a series of photographs showing existing bad conditions in New York's tenement houses. The rest of the exhibit illustrates housing conditions in other American cities.

A considerable part of the space allotted to this section is devoted to photographs of and literature concerning hospitals, asylums, public institutions, and universities. There are in the United States no fewer than 1,776 hospitals, sanatoriums, and dispensaries, a larger number than in any other country of the world. The hospitals, too, of the large American cities, on the whole, are not surpassed, and probably not equalled, by those of any land. It is therefore fitting that at a Pan-American Exposition, hospitals exemplifying the best types should be portrayed.

Such is the case, and the Roosevelt and Presbyterian, New York, Johns Hopkins, Baltimore, and Boston City Hospitals are excellently depicted, as to both their exterior and their interior features, in a series of well-taken photographs. A large model is also shown of a sick-ward in the Presbyterian Hospital, New York, and a smaller one of St. Mary's Free Hospital for Children, of the same city.

Homes and sanatoria for consumptives, State institutions for the insane, schools for the feeble-minded, soldiers' homes and almshouses, industrial schools, and children's societies are all represented by photographs, and their history, progress, and present condition set forth in a mass of literature. Elmira State Reformatory, its inception, rise and advance to the foremost position of any institution of its character, is particularly well portrayed both by reading matter and by photographs. The negro exhibit is of much interest; maps are displayed, showing the States according to their negro population.

The universities of the country, New York, Columbia, Brown, Harvard, Cornell, Chicago, Illinois, Princeton, Syracuse, and others, their buildings, methods of teaching, curriculum, etc., are portrayed by means of literature and illustrations.

The exhibits which make up the section devoted to public health and hygiene, hospitals, asylums, and public institutions are the most instructive of the entire Exposition, and should serve as an educational stimulus of no slight force.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 12, 1901.

Eosinophile Leucocytes and Nuclein Bases.—Edward T. Williams says that eosinophile leucocytosis is associated not only with the formation of spermine crystals, but with all the nuclein bases in the blood, marrow, glands, organs, tissues, or excretions. This fact has been demonstrated in at least four of the principal eosinophilous diseases, to wit, leucocythæmia, asthma, helminthiasis, and trichiniasis. Spermine crystals were found in splenic leucocythæmia by Charcot over forty years ago; in asthma by Salter, in 1860, though he did not know their chemical composition; in trichiniasis by Thayer and Brown, in 1897, but "guanine" crystals were found in trichinous pork by Virchow forty years earlier. Ankylostomiasis and several other worm infections have been shown to be characterized by eosinophilia and the presence of spermine crystals in the fæces. The presence of nuclein bases in eosinophilia proves that there is a decomposition of nuclein going on somewhere within the body. But nuclein is to be found only in nuclein-bearing cells. Nuclein-bearing cells, then, are undergoing decomposition in eosinophilia. The author suggests that these decomposing cells are the eosins themselves.

Climatic Treatment of Pulmonary Tuberculosis Versus Home Sanatoria.—S. G. Bonney enters a plea for climate as a therapeutic agent in tuberculosis, as opposed to the home sanatorium treatment which is now becoming fashionable. He says that the prevailing tendency to provide home sanatoria for all classes, and to repudiate the established facts of climatic influence, cannot fail to prove in the end a most unfortunate delusion. He regards it as especially opportune, at this time of local sanatoria agitation, "to reassert and emphasize the intrinsic distinctive value of climate, reinforced by proper living, as the all-important factor in the treatment of the disease." He fully admits the good results of sanatorium management, even in unfavorable localities, for early cases, but this should not be construed as an argument against the greatly increased benefits to be derived by a larger class of patients through removal to an appropriate climate. He argues that, if a suitable regimen without the favorable influence of climate is capable of producing a perceptible improvement in incipient cases, much greater and more lasting results will surely be obtained in a far greater number of cases when to precisely the same manner of life the beneficent influence of a suitable climate is added

New York Medical Journal, September 14, 1901.

Social Aspects of Dermatology.—In the first Lane Lecture Malcolm Morris outlines the plan to be followed in subsequent lectures of the course. He regards the skin as a microcosm of pathology in that on its surface may be seen not only the most varied expressions of internal disturbance, but examples, visible and palpable, of every process known to modern pathology, with its results immediate and remote. He reviews the founding of the science of modern dermatology, discusses the flora and fauna of the skin, the nervous factor in cutaneous disease, and the effect of skin lesions on the individual in his social relations. He says that a sound skin in presidents and princes is a guarantee of peace.

Professor Max Schüller's Views on Malignancy.—J. E. Blake reviews the recent work of the German professor entitled "Die Parasiten in Krebs," which in turn recounts the results of eighteen months' recent experimentation upon the parasite of cancer. The technical steps followed are given in detail. The substance of the conclusions reached may thus be stated: An organism has been isolated which can be grown in pure culture, which can be readily identified through its peculiar form, color, and mode of development, which occurs invariably in tumors, and which produces the same by its inoculation. There would, therefore, seem to be no reasonable doubt that these are the elusive parasites which have been so long sought. Whether any of the organisms previously described as occurring in tumors can be identified with the one here described, we do not know; but it is certain that this cannot be identified with blastomycetes or any other organism which grows on ordinary culture media, and is tolerant of a temperature that very rapidly proves fatal to the one just described. It apparently belongs to a class of animal parasites of which practically nothing is known. Certain researches of the author would tend to show that non-malignant tumors are produced by somewhat similar parasites belonging to the same class, and that under certain conditions these are either transformed into the malignant form or assume malignant qualities, which result in the same proliferation

of cells as that caused by the described forms. But of this too little is known to say anything definite.

Journal of the American Medical Association, Sept. 14, 1901.

Treatment of Certain Forms of Cancer by the X-Rays.—F. H. Williams believes that in the *x*-rays we have an agent which causes certain superficial external forms of cancer to heal, and that without pain. Photographs are presented of cases before and after treatment. The first case was one of epidermoid cancer of the lip, the second an epithelioma of the eyelid, and the third a rodent ulcer on the side of the nose and cheek. One photograph of a case still under treatment illustrates an epithelioma of the hand. The author is disposed to regard the action of the rays as something quite distinct from that of a mere cauterizing agent. The advantages of the method are absence of pain and healing without creating a burn. The disadvantages are that the necessary apparatus is heavy and expensive, that great care must be exercised in its employment, and that the treatment must often be continued for some weeks.

The Relation of Unbalanced Physical Development to Pubertal Morbidity as Shown by Physical Measurements.—W. S. Christopher presents statistics from the examination of several thousand school children. Elaborate tables of figures, charts, etc., are given. The following conclusions are offered: 1. There is an exaltation of life processes at the pubertal period which find its expression not only in an increased rate of growth, but also in the development of physical power. This exaltation commences earlier, and has a shorter duration in girls than in boys. 2. Puberty is also a period of great individualization, as indicated by the great normal range of physical measurements at this period. 3. The range of physical measurements at all ages in childhood, including puberty, is distributed uniformly above and below the line of average measurement. 4. At puberty mortality is low, and morbidity is high. 5. Neuroses, psychoses, neurasthenias, cardiopathies, deformities, and anæmias are the principal morbid manifestations of the physical, intellectual, and emotional turmoil which characterizes puberty. 6. The great range at puberty of the measurements of the physical features of the child expresses the condition which permits the existence in individual children of unusual lack of balance in physical measurements, or maladjustment of physical features. 7. Unbalanced physical development is an important factor in the production of morbid manifestations. It is found associated with most of the morbid manifestations of puberty, particularly disturbed heart action, dilatation of the heart, fatigue, anæmia, and some deformities, such as round shoulders and scoliosis, as well as many of the neuroses of the period.

Medical News, September 14, 1901.

The Treatment of Cystitis.—Charles Chassaignac enumerates the principal clinical types of this disease, but before considering them separately, he considers the general indications which apply to all forms to a certain extent. Rest is of the greatest value. Bland food alone should be used. In severe cases, milk, or milk and bread, is the best diet. Abundance of water is necessary. The bowels should be kept free by gentle laxatives. Hot baths are useful, as are also hot applications. Intravesical irrigations, with warm, mild antiseptic fluids, are of great benefit. The administration of alkalines is useful. Sometimes the administration of anodynes is demanded. The urinary antiseptics may be used, but with great caution, since irritation of the stomach and kidneys must be avoided.

Infantile Atrophy.—John Lovett Morse defines infantile atrophy as a morbid condition of infancy, in which there is extreme wasting of the soft tissues of the body, without demonstrable organic lesions. It rarely occurs after the first year, being most frequent during the first six months of life. It is seen more often among the poor than the rich, and more often in cities than in the country. It is probably due to some defect in absorption or assimilation. Little if any knowledge of this affection has been gained from pathological anatomy. Loss of weight is the most marked symptom. It must be differentiated from starvation, from gastro-intestinal diseases associated with wasting, from syphilis, and from disseminated tuberculosis. The prognosis is always grave. Treatment is mainly dietetic, while the laws of hygiene must be observed.

American Medicine, September 14, 1901.

Atropine as an Efficient Aid in Relieving Acute Pulmonary Œdema.—Charles O'Donovan believes that more lives can be saved by the hypodermic syringe than by the lancet. The dose required will be what is necessary to produce the physiological effect, and this is shown by the degree of dilatation of the pupil. A safe initial dose is $\frac{1}{100}$ grain, repeated in half an hour, or at longer intervals, until the system is under its influence. The action of atropine is well supplemented by strychnine. The danger of immediate death is not so great in this condition as in the case of weak heart. Still, necessity for prompt action is just as urgent. Time should not be consumed by giving remedies through the stomach, but the hypodermic method should be used.

A Note on Bacillus Coli Communis in a Possibly New Rôle as an Inhibitor of HCl in the Stomach.—G. W. McCaskey reports the case of a man aged thirty-one years, with a history of substernal and epigastric pain and failing health extending over a period of six or seven months. The stomach washings showed the ordinary cellular detritus of chronic gastritis, and almost a pure culture of Bacillus coli communis. A test breakfast showed an abundance of lactic acid without a trace of free HCl. After extreme care in washing out the stomach, the results showed not a trace of lactic acid, but 65° of free HCl. The writer offers three possible explanations: 1. The possibility of variation, due to neuropathic conditions. 2. The strong stimulation of the gastric mucosa by the irrigation. 3. The removal of immense quantities of Bacillus coli communis, which was in this case the undoubted producer of lactic acid.

Philadelphia Medical Journal, September 14, 1901.

Undiluted Milk in the Chronic Gastroenteritis of Rachitic Infants.—Maurice Ostheimer reviews several cases showing the development of rachitis with gastroenteritis of several months' duration due to the variety of food given and probably to its diluted character. Small amounts of pure, unboiled milk, undiluted, are undoubtedly indicated in cases of long standing gastroenteritis due to the administration of too large a quantity of too dilute food.

Unusual After-Effects of a Snake Bite.—Lawrence E. Holmes reports the case of a woman twenty-one years old who was bitten by a snake on the right forearm, about two inches above the wrist on the ulnar side. The variety of snake was uncertain. On the fifth day there was complete anæsthesia of the hand and wrist, anteriorly below the wound, posteriorly below the carpometacarpal articulation. The movements of the hand were impaired. In a few days the hand and arm gradually returned to the normal condition. Immediately after the injury, the wound was incised and washed out with a ten per cent carbolic acid solution. The problem presented itself as to whether this motor and sensory paralysis was due to hysteria or to a toxic neuritis.

The Employment of the Recuperative Power of the Heart as an Estimate of Its Functional Ability.—Martin Mendelsohn, in estimating the functional ability of the heart, ascertains the normal number of heart beats as a starting-point. This is done with the patient in a recumbent position. Then experiments by means of Gärtner's ergostats are conducted in order to discover to what degree a healthy heart is able to replace the materials used up in exertion. Every turn of the apparatus represents 1, 2, 3, or more kilograms of work accomplished, each turn occupying one second. At the end of the work the patient lies horizontally on the couch where the normal number of heart beats had been estimated. The experiments are repeated, sometimes three times, and only those results which agree with each other are considered. The following results have been obtained: 1. If a moderate amount of work, estimated by 100 to 200 kg., be accomplished by a person with a healthy heart, the increased pulse rate stops at once with cessation of the work, and again becomes normal. 2. If work between 200 and 500 kg. be done, the pulse rate becomes less very soon after cessation of the work, and may even drop below normal for two or three minutes. 3. If work averaging over 500 kg. is done, the heart beat continues to be increased above the normal, the degree of acceleration depending upon the amount of work accomplished. After some time the heart returns to normal, before which, however, it generally passes through a short period of subnormal frequency.

The Lancet, August 31, 1901.

Lessons to Be Learnt from Vegetable Pathology.—Jonathan Hutchinson, after a general comparison between disease processes as affecting the vegetable and animal kingdoms, counsels caution in the inferences which we draw, based upon an incomplete examination of facts, in reference to the different species of fungi which attack the human skin. There are a number of these fungi. One of them produces pityriasis versicolor; another causes true favus; another causes ringworm, and it is suggested that there are two or three kinds of ringworm. He would hint that we should be a little cautious in believing that

these diseases are not transmutable. His belief is that from the fungus of common ringworm of the scalp you can produce tinea versicolor, the common chloasma of the chest of an adult. He has seen many instances in which young nurses attending children the subjects of ringworm have developed, not ringworm, but tinea versicolor on the chest. He therefore suggests that we should be a little cautious in inferring, because the external appearances produced by the disease which we know as tinea versicolor, are different from those which we know as ringworm, and are diagnosable easily from each other, that the two things are not transmutable. After all, it may be a modification of the fungous growth, and it may be the same fungus which produces the two. His belief is that it is, and that the large fungus ringworm and the small fungus ringworm are very likely the same; and that the fungus which produces favus, which is very much less common, is only a very modified form of that which produces ordinary ringworm.

Note Concerning a Sign Often Associated with Early Phthisis.—W. Overend says that in cases which follow the ordinary sequence of initial deposition and consolidation within the upper lobes accompanied by dulness in the supraclavicular and supraspinal areas, a number of venous varicosities, one-third to two-thirds of an inch in length, may often be observed beneath the skin in the neighborhood of the spines of the seventh cervical and three upper dorsal vertebræ. They appear early and may become very conspicuous. At times they become apparent only after stretching of the skin laterally. Local pain is occasionally felt, also slight œdema may be found over these vertebral spines. This is considered due to the peculiar venous ramifications of this area. The sign appears to the author to be useful, and he has not come across it in any of the text-books and special treatises. The attention of the practitioner is at once arrested by it, and the condition of the posterior apices of the upper and lower lobes is then determined. The presence of auscultatory signs within this dorsal area, combined with wasting and myoidema, he believes, renders the diagnosis of early phthisis, even in the absence of sputum and bacilli, practically conclusive.

A Case of Spontaneous Gangrene in an Infant.—T. A. Bowes reports the case of a child, apparently healthy at birth, who developed on the thirteenth day a thrush from which it promptly recovered. Three days later it became peevish and would not nurse. Twenty-four hours later, a small vesicle was noticed on the buttock, which in twelve hours changed to a pustule. No trauma could be determined. The next morning the pustule had burst, leaving a small circular ulcer surrounded by a red zone which gradually spread to adjacent parts. From the ulcer there was a discharge of a thin, bloody, odorless serum. Later red and excoriated areas appeared on the fingers and about the umbilicus. The child died on the fourth day of the attack. Throughout the entire course of the disease there was no fever. An autopsy was not allowed. The case was believed to be one of spontaneous gangrene. Four similar cases which have been reported in literature are reviewed by the author. The only suggested cause of the affection is spasm of the arterioles of the affected area, and it appears doubtful whether this is of central or of peripheral origin, though changes in the spinal cord have been described in some cases wherein the disease has been symmetrical. In explanation of the gangrene following the diseases above enumerated it is suggested that there is a local infection by the microbes of the disease in the presence of a lowered vitality of the subject. The noteworthy features of the present case were: the absence of any severe initial symptoms, the fact that the temperature was never raised above normal, and the extreme rapidity with which so large an area of skin was involved, the whole duration from commencement to the fatal issue being only three and a half days.

On the Prophylaxis of Carcinoma.—C. B. Keetly says that if we grant that the cause of carcinoma is a living organism, the situations generally attacked by the disease suggest first, that its cause flourishes in either the secretions or the cells of the skin-glands, including the mammæ, *e. g.* butter, milk, and cheese, sebaceous material, and sweat, and second, that before butter, milk, and cheese are allowed to rest in contact with weakened parts, *e. g.* ulcerations, either inside or outside the body, such articles of food should be sterilized by heat, while the secretions of the skin-glands should be kept away by cleanliness. With regard to the occurrence of carcinoma in certain occupations (chimney-sweeps, pipe-smokers, workers in petroleum, etc.), it is to be said that these occupations lead to the production of a chronic eczema, and that this furnishes a proper soil for the growth of the carcinoma parasite. He therefore lays down the following hygienic and dietetic rules as conducive to the restriction of carcinoma: 1. Chronic inflammations, suppurations, and especially ulcerations, should not be neglected or allowed to drift. Still better, commencing troubles of the kind should be treated promptly and not allowed to become chronic. 2. Well-known sources of irritation of mucous membranes and of skin should be avoided, *e. g.* smoking when any trace of soreness is discovered in the mouth, on the tongue, or on the lips, and the habitual use of strong condiments and spices. Workers in special trades, such as chimney-sweeping, should lose no time in having the smallest cutaneous rashes or other trouble promptly cured. Among milk products cheese is itself an irritant to mucous membranes. 3. A woman should allow nothing to come in contact with her nipples except smooth, clean linen, cotton or silk, and the soap and warm water with which she washes herself. After being washed, the nipples should be gently and thoroughly dried. She should not touch them with her hands or fingers at all. During lactation the nipple should be cleaned and gently dried after each act of suckling, and then protected with a dry and clean covering. The nipple should not merely be withdrawn from the infant's mouth and pushed back under the mother's clothes. If wool be worn it should be sterilized by heat. 4. Whoever takes, as food, uncooked and unsterilized milk, butter, and cheese should recognize that he does so at the risk of introducing into his system the germs of disease, and that among these disease-essences, so to call them, may be that of carcinoma.

Tuberculosis, Bovine and Human.—F. Hueppe vigorously combats the views advanced at the recent London Congress by Robert Koch. Because the bacillus of man has no hold on the ox, Koch assumes the tubercle bacillus of man and of the ox are of different species. This is, says Hueppe, a bald statement, and he himself utterly repudiates any such conclusion. The histological differences between miliary tubercles in the human subject and the tubercles of Perlsucht in the ox, which differences, however, the majority of pathological anatomists do not deem of such importance as Virchow does, indicate a dissimilarity in the inherent quality of the tissue; but whether this inherent quality will attain its remote or ultimate developments by easy processes or by difficult ones, by the operation of pathogenic agencies of like kind or of unlike kind—on these points the histological appearances supply no data for the formation of an opinion. Only bacteriological experiment can throw light upon the question of communicability and can explain whether in the course of inoculated disease or natural infection a biological or morphological modification and adaptation of a parasite of like kind takes place, or whether only parasites of unlike kind have to be reckoned with. The differences which Virchow discovered long ago and the distinctions which Koch has now found to exist are concerned with quite different things—the one with the inherent quality of the structure and the other with the remote or ultimate developments dependent thereon—and the facts ascertained with regard to one of those do not necessarily serve for the elucidation of the other. The cattle bacillus certainly affects the human subject. We are in fear that it will be communicated to us by the milk of tuberculous animals. The channel of contagion is not the gastroenteric tract so often as is supposed, but is very frequently the tonsils. It therefore appears possible that when fluids containing pathogenic organisms are drunk these organisms make their way into the system from the upper passages—the tonsils—and then the primary focus of the disease is in the region of the air passages; it is under these circumstances a mistake to suppose that there is an infection of the lung through the respiration. For this reason Hueppe has a suspicion that many forms of tuberculosis are at present erroneously ascribed to respiration, whereas they ought to be attributed to infection from food, especially milk. Hueppe is not disposed to relax any of the precautions of modern years in reference to the use of milk and meat. He says that when cattle are allowed to graze at liberty, uncooked milk may be taken with impunity. But in low countries and towns where cattle are herded together in damp cow-houses and infection spreads from animal to animal, Koch's assertion that there is no cause for uneasiness would be an invitation to carelessness which would undo all that has been accomplished. We ought to carry on the struggle against bovine tuberculosis unremittingly, both on account of the economic danger and also because bovine tuberculosis forms an immediate danger to mankind. The question is not whether this danger is great or small, whether it has been overestimated formerly or is underestimated by Koch now; but what has to be considered is that this danger comes upon us in a form which requires the most energetic measures of public hygiene, because the inhabitants of towns, especially the workers in manufacturing towns, are quite unable individually to protect themselves sufficiently against it.

British Medical Journal, September 7, 1901.

The Value of Widal's Serum Reaction in the Diagnosis of Typhoid Fever in Children.—J. H. Thursfield believes that the use of Widal's serum reaction makes the diagnosis of typhoid fever a certainty, and serves to eliminate doubtful cases. There is a certain fever among children which, although it strongly resembles typhoid, does not run the normal course, nor present quite the symptoms of typhoid. It is a source of error in the diagnosis of typhoid. This method will probably yield even better results in the future.

What Is Intussusception, and How Should It Be Dealt with?—Edmund Owen defines this affection as the catching up of one piece of bowel within another piece. The symptoms are, generally, severe pain, vomiting, scanty liquid fæces mixed with mucus and blood. The bowel may not be distended; there may be some diarrhœa. The distress is paroxysmal. If the abdomen is flat, there may be felt a lump in the region of the ascending colon. Surgical treatment, without question, is the best way of affording prompt and certain relief.

Ultimate Results of Tendon Grafting in Infantile Paralysis.—Sinclair White's experience in tendon grafting includes eleven cases. One of these had to do with the extensor muscles of the thumb, the others being cases of foot palsy. Although he thinks that the first case is almost a failure, a large part of the cases have received great benefit. As a general rule, it is better not to operate till the age of four years or later. The limb must always necessarily be to a certain extent weak. It takes time to develop the full benefit of the operation. He believes that this method is a valuable addition to surgery.

On Essential or Toxæmic Dropsy; Dropsy Without Albuminuria.—W. P. Herringham states that the term idiopathic or essential dropsy is the term given to those cases of general anasarca which exactly resemble cases of Bright's disease, only that there is no albumin in the urine, and no abnormal cardiac condition. It is more common in children than in adults. This affection is often preceded by a chill and is frequently secondary to scarlatina. Some cases begin with marked symptoms, others insidiously. The amount of urine varies. There are no constant anatomical lesions. The kidneys are normal to the naked eye. The writer believes that there are many cases of general dropsy which are not cases of nephritis. In some cases there is no anæmia. This affection is undoubtedly due to a toxic condition of the blood, in which the kidney has not been inflamed. The writer advocates in the treatment the use of syrup of the iodide of iron, drop doses of the liq. arsenicalis, and the administration of milk and digitalis to increase the flow of urine, which will both decrease dropsy and purify the blood.

Two Cases of Chronic Hydrocephalus in Infants Treated by Tapping and by the Introduction of Aseptic Air in the Place of the Fluid.—Wm. Ewart and W. Lee Dickinson conclude that, with due precautions, the fluid of chronic hydrocephalus may be completely evacuated from the yet unclosed skull of infants, and aseptic air may be allowed to take its place. This operation may be repeated without detriment, and with scarcely more risk than belongs to the usual method of paracentesis. In favorable cases of moderate effusion a single operation may suffice. Continued oozing from the puncture for a few days after the removal of the tubes is not unfavorable. In cases of considerable effusion an obvious indication is to relieve the brain from the weight and pressure of the fluid. The evacuation is facilitated by the introduction of aseptic air. By a timely repetition of the operation, a hydrocephalic infant might be enabled to carry the weight of the head, and if the treatment were sufficiently early, permanent damage to the brain tissue might be averted, and a normal development might perhaps ensue. In large heads, whilst hydropneumocephalus persists, a considerable risk is run in eliciting this sound by forcible succussion, and for the same reason any abrupt movement of the head should be avoided.

Berliner klinische Wochenschrift, August 26, 1901.

The Compression Treatment of Heart Disease. M. Mendelsohn says that in all cases of cardiac disease, accompanied by dilatation of the left ventricle, much may be effected by a carefully fitted bandage, with a pad over the præcordium, making firm pressure in that region. When there is much dilatation the heart loses the natural support it gets from the lungs, which normally almost envelop it, and, consequently, there results undue traction on the great vessels and other structures at the base, and, in addition, the bare thoracic wall is exposed to constant jarring and pressure, which is responsible for much of the subjective discomfort attending these cases. The apparatus used by the author consists of a metal plate, molded to fit from a plaster cast of the chest, and supplied with a small air cushion, intended to be inflated after the whole has been strapped in place, the patient thus being able to graduate very accurately the amount of pressure exerted.

Tuberculosis in Man and Animals.—F. Hueppe takes a stand which is opposed to the recent dicta of Koch as expressed at the British Congress, and gives due credit to the American workers whose observations antedated those of Koch by several years. An important point, which has so far been left untouched, is the fact that, even granting that the bacillus of human tuberculosis could not be made to take root in the animals experimented on, it does not necessarily follow that this is true for all species of cattle. For example what was long held to be the anthrax of swine was shown to be a wholly different form of septicæmia, and then it was supposed that the true disease was not transmissible to these animals, yet subsequent investigations proved that certain species were susceptible. The fact that human tubercle bacilli do not infect cattle does not justify us in concluding that there must be two separate forms of organism, as Koch infers, for the same mistake was made in regard to the bacteria of the tuberculosis of mammals and fowls. These were thought to differ specifically until the researches of F. Fischel, and the author showed that it was possible by cultural modifications to effect the infection of animals of each type with the organism of the other class. The tubercle bacillus, undoubtedly, has the power of adapting itself to its host, and for the time being developing a greater predilection and power of infection for that particular species, whether it be rabbit or ox or man, but it can also readily adapt itself to new conditions and develop its usual virulence under altered conditions; thus a bovine bacillus is easily capable of infecting a susceptible human being—a child, for example. Primary infection of the intestine is not nearly so rare as the figures given would indicate, and, besides, it has been shown that alimentary infection does not always primarily attack the digestive tract, but that bacteria introduced with the food may find a lodging-place on the tonsil, whence access to the respiratory passages is easy, and it is probable that many infections which have been ascribed to inhalation were contracted in this way.

Münchener medicinische Wochenschrift, August 27, 1901.

Auscultatory Percussion.—J. Hofmann describes an apparatus he has devised by which percussion can be performed with a single hand. It is a combination of plessor and plexímeter, the hammer being pivoted so that when elevated by the pressure of a finger on its handle and then suddenly released, a blow, the intensity of which can be graduated by the use of the attached angular scale, is struck upon the pleximeter, which is a plate of hard rubber covered with a layer of soft rubber. The apparatus is intended for use with the phonendoscope, and by comparison has been found to give just as accurate results as those of the more elaborate and difficult method of friction auscultation. By this means liver and heart dulness may be differentiated and even the limits of the lower lobe of the right lung may be determined.]

The Etiology of Erysipelas and Its Relation to the Pyogenic Infections.—Jordan says that the distinction of true and false erysipelas is a doctrine no longer tenable, for many clinical varieties of the disease occur and etiologically there is no difference between them. It is rather a question of varying degrees of intensity of the same disease depending on the inconstant virulence of the cocci and the resistance of the tissues. The specific nature formerly ascribed to the disease can no longer be upheld, and in origin, nature, course, and complications it bears a close analogy to acute osteomyelitis. Several cases are cited and references given which show that although it is usually a streptococcus infection, staphylococci may also produce the typical picture of the disease, and experiments are described showing that in the rabbit's ear it is possible to produce typical erysipelas not only with streptococci, but also with staphylococci, pneumococci, and bacteria coli. Human erysipelas is usually caused by the streptococcus pyogenes, but may also be due to the staphylococcus aureus, and it is still an open question whether pneumococci, bacteria coli, and typhoid bacilli may not also produce it.

Two Cases of Latent Sinus Thrombosis Following Middle-Ear Disease.—Holscher reports two cases which are interesting because of the sluggish course run by an affection which ultimately, in both instances, led to an empyema of the mastoid process. In the first case, occurring in a boy of sixteen, the middle-ear inflammation at its onset was accompanied by painful swelling behind the auricle, with severe headache, dizziness, and vomiting, but no

perforation of the tympanum; after the subsidence of the acute symptoms the headache and vertigo continued for some time, but there was no indication of progressive trouble, and it was not until twelve weeks later that mastoid symptoms developed and led to operation. The second case, in a middle-aged man, ran a still more sluggish course, the patient not coming under observation till five months after the beginning of his ear disease. The acute symptoms had all subsided and a small perforation afforded sufficient drainage for the scanty discharge. A slight afternoon fever was present, but yielded readily to palliative measures and no indication for operation manifested itself for three months more. In both instances, on operation, a sinus thrombosis was found which apparently dated back to the original acute suppuration and then gradually underwent granular degeneration, finally leading to abscess formation.

Deutsche medicinische Wochenschrift, August 22-29, 1901

Further Communications on the Angina Due to the Spirochæte Bacillus.—H. Solomon reports that, though very rarely associated with true diphtheria, this organism is often found in syphilis of the throat. A study of the statistics of the city of Frankfort, covering 737 cases in which throat cultures were made, revealed the presence of the spirochæte bacillus in but three, and in none of these, nor in those described in the literature, was it found together with the bacillus of diphtheria. It may therefore be concluded that when the presence of the spirochæte flora has been discovered, diphtheria may almost with certainty be excluded—a fact of some practical importance. In specific disease of the pharynx, however, the organism occurs with comparative frequency and in two cases, which are described in detail, formed what was clinically speaking the primary lesion; it was only after the disappearance of an obstinately persistent membrane that the tonsils became fissured, and true mucous patches developed. In but one case of stomatitis was the bacillus found; this was in a boy of five, suffering from aphthous stomatitis which showed almost pure cultures of spirochætæ and bacilli fusiformes.

Rectus Abscess in Typhoid Fever.—L. Bollack and H. Bruns describe the case of a young man who, during his convalescence from typhoid fever, after a fit of coughing, developed a painful swelling of the right rectus muscle. As soon as fluctuation was made out, the tumor was incised, and a quantity of yellowish brown pus evacuated. Two weeks later a similar mass appeared on the opposite side, but receded and underwent complete absorption without operative interference. Cultures and animal inoculations from the pus obtained showed the presence of typhoid bacilli in pure culture, and the assumption is that the recti muscles, having undergone a certain amount of granular degeneration as the result of the disease, ruptured, and the subsequent extravasation of blood afforded a suitable culture medium for the development of the bacilli. In this, as in other cases reported, the organism was greatly reduced in virulence, which perhaps has some connection with its pus-producing faculty, while the assertion that such accumulations usually run a benign course was corroborated. It seems, therefore, that in such cases, when an abscess or empyema contains typhoid bacilli in pure culture, conservative treatment, and not surgery, is indicated, as absorption unattended by by-effects is likely to take place.

Injury and Diabetes.—F. Hirschfeld considers the relation of trauma to this disease, and the extent to which accidents may be held responsible for its production. A distinct connection between the two is often traceable, particularly in the case of diabetes of nerve origin, in which the central nervous system appears to be implicated, and which is not infrequently susceptible of cure or improvement. When there already exists some lesion of the pancreas, the possibility is far from remote that a trauma might set up sufficient disturbance to precipitate the onset of diabetic trouble, while accidents may be the cause of pancreatic lesions themselves, such as cysts, hemorrhages, and, possibly, chronic inflammations. Long-standing diabetes may be unfavorably influenced by shock, the severest contingency to be feared being the inauguration of coma. In rare instances, even when the disease is only slight, coma may be precipitated in this way, and doubt may then exist as to whether the condition is due to the accident or the constitutional trouble. There is often great difficulty in deciding as to the proper valuation of trauma and disease in the production of gangrene, though even a trifling injury may be productive of serious results in a but slightly diseased vascular system. Muscular capacity is greatly decreased in diabetes, and patients belonging to the working classes are usually to be considered as being incapacitated.

The Effect of Pregnancy and Labor on the Phthisical Process, and the Therapeutic Value of Artificial Abortion.—S. Kaminer cites the opinions of various observers which are rather contradictory. The two most radically opposed authors are Kleinwachter and Maragliano. The former sums up his indications for the induction of abortion by saying that it should be performed only when conditions prevail which are directly caused by the pregnancy, and jeopardize the life of the mother, and can be relieved only by this measure, thus totally excluding tuberculosis. Maragliano, on the other hand, says that abortion should always be performed, and the earlier the better, since in this way, in addition to the advantage to the mother, who is relieved from the risks of labor, mankind is benefited by the removal of a future tuberculous unit from society. Out of fifty cases collected by the author, in sixty-six per cent. the pregnancy reacted unfavorably on the mother; and inasmuch as labor is always a severe exertion, making undue demands on the enfeebled system of a consumptive, he believes that in many cases the induction of abortion is indicated, since it does away with the dangers of pregnancy, and when skilfully performed its effects are in no way comparable with the severe stress of an ordinary labor. Maragliano's sweeping statement, however, is too far reaching, and no definite rule can be laid down, but each case must be judged separately and treated accordingly.

French Journals.

Surgical Treatment of Enteroptosis.—Lambotte states that surgical intervention aims to remedy the partial or total prolapse of the colon, and the trouble so caused in the passage of fæces. The operation consists essentially in the fixation at the two sides of the angles of the transverse colon. A series of sutures is made through the abdominal wall. The writer has obtained happy results in the majority of his cases.—*Gazette Hebdomadaire*, August 29, 1901.

The Swallowing and Discharge of a Large Pin Without Accident by the Natural Ways.—Albert Peillon reports this case. The patient was a girl of fourteen years. She swallowed a large pin, head first. She was given soft bread at once by her mother. The writer watched the case from day to day, and on the fourth day after the accident the pin was discovered in the stools. The writer thoroughly believes in the expectant treatment in these cases. Soft, bulky food should be given.—*Lyon Médical*, August 18, 1901.

Treatment of Acute Mucous and Dysenteric Colitis in Children by Sulphate of Sodium.—According to E. C. Aviragnet, the results obtained by the use of sulphate of sodium in these affections are remarkable. Its action on the secretions of the large intestine is wonderful and constant. In a large dose it acts like all purgatives, in a small dose it causes the glairy and bloody hypersecretion to disappear. The dose advised is fifteen grams the first day, and small doses on the following days—five grams, for example, in a child of twelve to fourteen years; two grams in a child of two years. The administration should be continued more or less for eight days. The salt is given in a glass of sweetened water. All of the unfavorable symptoms are rapidly ameliorated.—*Gazette Hebdomadaire*, September 1, 1901.

Acute Occlusion of the Small Intestine in the New-Born from Congenital Deformity.—E. Weill and M. Péhu believe that the diagnosis of this affection is generally easy. The symptoms are: vomiting of meconium, absence of evacuation of meconium, absolute constipation from birth, and more or less marked abdominal distention. In stenosis of the œsophagus there is almost immediate expulsion of the milk and no abdominal symptoms. In stenosis of the pyloric orifice there is vomiting of curds, but no fecal matter, and no bile. In the first affection there should be a careful examination of the rectum by finger and by catheter, in order to be certain that there is no occlusion of the lower part of the digestive tube. All measures must be taken to fix, if possible, the position of the occlusion, before treatment is begun.—*La Presse Médicale*, August 17, 1901.

Surgical Treatment of Hydatid Cysts of the Kidney.—Albarran concludes: 1. If laparotomy has been performed in the absence of clear diagnosis, nephrotomy is indicated with rare exceptions. 2. If, with or without a clear diagnosis, it is decided to make use of the lumbar route, the cyst should be opened, and it should be decided at once as to the possibility of extirpating the germinative membrane. If that is impossible, the condition of the kidney should be observed: (*a*) If the kidney is still useful, and it is possible to extirpate the cyst totally, a renal resection should be made. (*b*) If the kidney is still useful, and that operation is impossible, nephrotomy should be practised after partial resection of the cyst. (*c*) If the kidney is useless and unfit for any further function,

nephrectomy is indicated. If the k[illegible] so firmly imbedded that great injury would be done by this proceeding, then nephrotomy will have to be resorted to.—*La Presse Médicale*, August 24, 1901.

International Medical Magazine, July, 1901

Feeble and Premature Infants.—Floyd M. Crandall would have the child wrapped in absorbent cotton or cotton batting and a blanket, not bathed, nor even sponged if very feeble, but rubbed with oil daily, and kept in a very warm but well-aired room. Food will have to be given through a medicine dropper or by means of a teaspoon (breast milk when possible), and the child be put to the breast as soon as it has strength to nurse. When the feeding is difficult and cow's milk must be used, complete peptonizing will prove very satisfactory.

Obesity Treated by Systematic Movements.—John Madison Taylor disapproves of the adoption of a marked change of diet in the case of many persons who thus endeavor to reduce obesity. He recommends instead a set of regulated exercises, consisting of respiratory movements, correct standing position, and bending forward until the hands touch the floor, the legs and pelvis remaining in their former position, the trochanters being used as the pivots, after which the pelvis is allowed to follow the line of the straight back; extension of the arms, movements on all fours, etc., etc. A quarter of an hour morning and night of these exercises is sufficient to bring about a decided loss of fat, with restoration of symmetry and activity to bulky and awkwardly shaped people. Marked improvement in general vigor and organic activities also follows.

Causes, Symptoms, and Diagnosis of Chronic Intestinal Catarrh.—Boardman Reed says in regard to the diagnosis of this affection, that the greatest difficulty will be found in differentiating it from nervous forms of diarrhœa resulting from vasomotor paresis. In genuine nervous diarrhœa there is no mucus, and there is rarely any pain; the stools are not fetid, no indicanuria nor excess of the aromatic sulphates is likely to appear in the urine, and the attacks are usually transient as well as coincident with an increase in the other neurasthenic or hysterical symptoms. If such diarrhœal attacks recur often, and particularly if they incline to linger for days at a time, it may well be suspected that a catarrhal process has been set up. Constipation from stricture, tumors, etc., is to be differentiated also, but when these persist long a catarrhal process nearly always results. Intestinal catarrh is by no means synonymous with diarrhœa, the majority of cases being accompanied, at first at least, by constipation.

The Treatment of Cholera Infantum.—W. Blair Stewart urges the exhaustive physical and dietetic study of each case, and bids the physician remember that in treatment *elimination* is first; diet second; hygiene and change of air third, and antiseptics and astringents the last in importance. Calomel and a full enema of the starch mixture is often all that is needed in the way of medicinal treatment. When there has been purging but no vomiting, a teaspoonful of equal parts of castor oil and aromatic syrup of rhubarb every two hours until a full yellow stool is obtained will answer. For cases with obstinate nausea and vomiting give hydrarg. chloridi mit., grain $\frac{1}{10}$; pulv. ipecac. et opii, grain $\frac{1}{16}$, and bismuthi subgallat., grain 1. Give one such powder every one-half to one hour. Sea air, with slight assistance from medicines, will often work wonders. Give all the fresh air possible; do not hold the child in the arms, nor rock it, but place it in a cool, solid bed. Always starve these patients for the first twelve to twenty-six hours.

Treatment of the Febrile Stages of Gastro-intestinal Disorders in Children.—W. C. Hollopeter says that the keynote of this treatment is the absolute cleansing of the gastro-intestinal canal of all bacteria and material that generates bacteria; the administration of sterile food, the combating of tissue-waste; absolute quietude, and the rigorous attention to the management of the slight details of this condition. The author's plan is usually to empty the stomach and then to give a slight enema of, say, a teaspoonful of glycerin to a tablespoonful of warm water; then a high enema of one quart tepid water and one tablespoonful of sodium bicarbonate; next, broken doses of calomel until the characteristic stool is found, and then a dose of castor oil. All solids and all milk foods should be withdrawn and albumen water, or toast water or gum water given. Medication after the first twenty-four hours of calomel and the oil should be a mixture of bismuth subnitrate, 2 grains; sodii, $\frac{1}{2}$ grain; aromatic powder, $\frac{1}{2}$ grain; sugar of milk, 1 gram; dry on the tongue every two hours, or with every movement.

The Edinburgh Medical Journal, July, 1901.

The Capillary Reflux and What We Learn by Observing It.—Alexander Haig says that the capillary reflux is the flowing back of the blood into the capillaries of a portion of surface skin rendered anæmic by pressure, and the rate of this reflux is a measure of the quantity of uric acid in the blood, because the uric acid controls the capillary circulation. He gives the methods of measurement which he has adopted, by means of which a known pressure is applied to a known surface for a definite time, and the time accurately measured which it takes the blood and color to make a complete return. The curves illustrating the article show the effects of cold on the uric acid in the blood, the effects of feeding uric acid by taking foods that contain it, and the fluctuations produced in the capillary reflux by salicylic acid and its salts.

The Experience of Forty-two Cases of Goitre Treated by Operation.—A. Marmaduke Shield concludes from his experiences that medical treatment should not be neglected in cases of goitre. The administration of iodide of potassium with tincture of iodine, in the proportion of three grains of the former with one minim of the latter in infusion of gentian, three times a day, may cause small goitres to disappear entirely. Goitres which tend progressively to increase should be operated on before they grow to a huge size, and before their deep connections become complicated. Removal of one lobe and the isthmus is practically always followed by atrophy of the corresponding lobe. The operation is free from special risk if done properly, and with the assistance of an experienced anæsthetist. Large, old, adherent goitres still remain difficult and dangerous to remove. It is the duty of every practitioner to urge this upon his patients, and submit them to operation while removal is yet comparatively safe and easy.

Deutsche Zeitschrift für Chirurgie, July, 1901.

The Removal of Foreign Bodies from the Lower Portion of the Œsophagus through the Stomach.—Wilms describes a method of reaching the lower end of the œsophagus for the manual extraction of foreign bodies which overcomes some of the difficulties that have heretofore been experienced. If the abdominal and gastric wounds are made sufficiently large to permit the entrance of the whole hand into the stomach, the risk of infecting the peritoneal cavity is very great, while on the other hand, if the opening be made large enough for the entry of only a single finger, as usually performed, the operation does not permit easy access to the cardia and œsophagus. The author incises in the middle line, but draws down a portion of the fundus instead of opening the stomach in the customary way at the pylorus. A small incision just large enough to permit the index finger covered by a finger cot of thin rubber to force its way in is made, and the opening tightly closed around the finger by the tightening and knotting of a previously applied purse-string suture, encircling it. The stomach wall may now be completely invaginated, and the hand carried close up to the cardia giving the finger inside easy access to the œsophagus without the slightest danger of any infectious matter escaping into the abdomen.

An Unusual Case of Resection of the Stomach.—F. Franke's patient had the advanced age of seventy-nine years, and a number of complications occurred both during the operation and convalescence. While under observation for a not very troublesome nor very long-standing gastric disturbance, a tumor developed in the left hypochondrium and the diagnosis of carcinoma was made. On operation it was found that the growth was much larger than had been expected, and it was at first thought that a gastroenterostomy was as much as could be done. This was accordingly made, but the patient's condition remained so good that the tumor was resected and duodenum and pylorus closed in the usual way. It was then seen that the stomach wall near the site of suture gave the appearance of being of very poor vitality, and the whole line of suture and a portion of the surface was enveloped in omentum and this sutured in place as a safeguard. The gut at the point of anastomosis with the stomach was then seen to be bent at so sharp an angle that an enteroenterostomy was done between the two loops. The patient recovered well from the operation, but subsequently developed a pneumonia followed by empyema which protracted convalescence, but finally he was completely restored to health. In considering the causes of the pneumonia that so frequently follows gastric operations the author thinks that Stendel's theory ascribing the trouble to the very firm dressing necessary in such cases affords the most probable explanation.

Book Reviews.

THE DIAGNOSTICS OF INTERNAL MEDICINE. A Clinical Treatise Upon the Recognized Principles of Medical Diagnosis. Prepared for the use of Students and Practitioners of Medicine, by GLENTWORTH REED BUTLER, A.M., M.D., Chief of the Second Medical Division, Methodist Episcopal Hospital; Attending Physician to the Brooklyn Hospital; Consulting Physician to the Bushwick Central Hospital; formerly Associate Physician, Department of Diseases of the Chest and Diseases of Children, St. Mary's Hospital, Brooklyn, N. Y.; Fellow of the New York Academy of Medicine; Member of the Medical Society of the County of Kings, etc. New York: D. Appleton & Company, 1901.

THIS volume presents some unusual features and will find many readers who will appreciate the method by which the subject is treated. The great bulk of the work deals with the evidences of disease, and does so in a most satisfactory manner. The student is taught how to proceed in the examination of his patient, what routine questions are to be asked such as would lead to a preliminary opinion which in turn would suggest certain examinations in detail. The author teaches not only what to do, but how to do it, and his advice and method of diagnosis are to be highly recommended. The smaller details, which only acute observers notice, are pointed out and their significance is weighed. It will be of service as a reference book in suggesting explanations in cases where but one or few symptoms, not pathognomonic, are presented for diagnosis—for each symptom is explained and the ordinary diseases in which it occurs are mentioned, while in the latter part of the book the diseases are treated separately, so that direct suggestions can be immediately considered without consulting another volume. All the modern laboratory methods are well described, the chapters on the blood and stomach contents being especially good, though brief. The thorough modernness of the instruction is well instanced by drawings of the culex and anopheles genera of mosquitos.

The author is evidently fully conversant with the clinical evidences of disease, for his treatment of the chapters on the signs and symptoms which present themselves in the patient is unusually well balanced with reference to their importance. The section on pain is very thorough, the illustrations are profuse and particularly instructive. The author is responsible for the larger part of the work, but has apportioned the part on Parasites and Intoxications to Dr. Frank W. Shaw; that on Diseases of the Kidney and Constitutional Diseases to Dr. Henry G. Webster; that on Diseases of the Blood and Ductless Glands to Dr. Henry P. De Forest, and that on Diseases of the Nervous System to Dr. S. E. Teliffe, and Dr. A. B. Bonar. A special feature of the work throughout is the unusual profuseness of plates and diagrams. Wherever these would seem to be of use in making the text more clear, they have been freely employed, and are well chosen.

A MANUAL OF SURGICAL TREATMENT. By W. WATSON CHEYNE, C.B., M.B., F.R.C.S., F.R.S., Professor of Surgery in King's College, London, etc., and F. F. BURGHARD, M.D. and M.S. (Lond.), F.R.C.S., Teacher of Practical Surgery in King's College, London, etc. In seven volumes. Vol. V. The Treatment of the Surgical Affections of the Head. Face, Jaws, Lips, Larynx, and Trachea, and the Intrinsic Diseases of the Nose, Ear, and Larynx, by H. LAMBERT LACK, M.D. (Lond.), F.R.C.S., etc. Philadelphia and New York: Lea Brothers & Co., 1901.

THIS is the fifth and so far largest volume of the excellent work of which it is a part. The title page is so comprehensive that it is hardly necessary to give further particulars as to the contents of this section of the work. It will be seen that there are several chapters on subjects of more interest to the specialist in certain departments than to the general surgeon, but this is no objection to the book from the latter's point of view. The diseases and injuries of the scalp and the skull receive attention first, and we may note a very terse and satisfactory description of the treatment of fractures of the skull, especially from the operative point of view. There is also a very complete discussion of the characteristics and treatment of various intracranial conditions the result of injury and disease. The so-called operation of craniectomy is mentioned and very properly not recommended. In the chapter on cerebral localization there are some very good illustrations, and what is said on the subject of tumors of the brain is sound and conservative. In discussing lupus, the old classification is adhered to, and the new treatment by heatless light is commended. There is an interesting chapter on trigeminal neuralgia, with accurate descriptions of the more extensive operative procedures.

In discussing cleft-palate the authors [illegible] favorably of the comparatively recent [illegible] suggested by Davies Colley, which apparently [illegible] good results more probable after what is usually a [illegible] what unsatisfactory operation. Tumors of the [illegible] form an interesting subject and in this work we [illegible] offered an excellent classification, as well as a [illegible] hensive survey of the different modes of treatment [illegible] operations. The illustrations in this part of the [illegible] are rather scanty.

In malignant diseases of the larynx it is [illegible] that complete laryngectomy be done whenever there [illegible] the least suspicion that the disease has spread beyond [illegible] one-half the organ, and very complete directions [illegible] the performance of the operation. The anatomic lesions [illegible] and nasal fossæ have been turned over to a specialist and the same is true of the ear and the parasitic diseases of the larynx. On all these subjects, the information given is more than sufficient for the general worker and often enough for the specialist. When the present work is completed, it bids fair to be a complete cyclopædia of surgical information.

APPENDICITIS, ITS PATHOLOGY AND SURGERY. By CHARLES BARRETT LOCKWOOD, F.R.C.S., Assistant Surgeon and Lecturer in St. Bartholomew's Hospital, etc. London and New York: Macmillan & Co., 1901.

THIS monograph is one of the most satisfactory on its subject which we have seen. The author has endeavored to present the subject of appendicitis in the light of his personal experience, and, since many patients have come under his care, the result is gratifying. He gives a short but complete chapter on the anatomy of the appendix, and then discusses the pathology of the organ, giving views which coincide with what we in this country, have come to consider correct. He rightly objects to artificial classifications. The subject of treatment includes many descriptions of cases operated upon by the author himself, and his ideas here are in accord with the most enlightened opinion. The subject of appendicitis has not received in England, as a rule, the intelligent treatment which we think it deserves, and it is consequently refreshing to read English opinions which might be American. This writer does not quite set forth the advantages of the interval operation, but he describes the different methods and mentions successful cases. The illustrations are excellent, and the book is very well printed.

THE HYGIENE OF TRANSMISSIBLE DISEASES. Their Causation, Modes of Dissemination, and Methods of Prevention. By A. C. ABBOTT, M.D., Professor of Hygiene and Bacteriology, and Director of the Laboratory of Hygiene, University of Pennsylvania. Second Edition, Revised and Enlarged. Philadelphia: W. B. Saunders & Company, 1901.

THE appearance of a second edition is a substantial proof of the interest with which this work has been received. Although the plan of the original volume has not been changed, there have been many additions, and modern views have been substituted where the original ones do not embody the latest researches. The subject matter deals essentially with that department of hygiene which embraces a knowledge of those specific diseases, concerning the prevention of which modern research has taught us so much. Besides the special consideration which is paid to the various individual diseases herein discussed, questions relating to general sanitation are also taken up. Particular attention is paid to the discussion of the rôle of insects and of rodents as disseminators of disease. Much new work has been done in the sections on malaria, yellow fever, plague, filariasis, dysentery, and tuberculosis. Both the predisposing and exciting causes of disease are discussed. The list of special diseases which are considered in relation to their causation, modes of dissemination, and prevention is a long one. Under general prophylaxis, the author treats of immunity, vaccination, and protective inoculation. Disinfection and disinfectants are treated in considerable detail. Quarantine is touched upon. The book is concluded by an excellent index.

Diseases and Their Odor.—MacCarry (*The Australasian Medical Gazette*) says that every physician should be able to diagnose certain diseases by their odor, that of mice in favus, peculiar acidity in rheumatism, nauseous breath in pyæmia, putridity in scurvy, musk in peritonitis, sour beer in scrofula, ammonia in simple fever, new bread in intermittent, and violets or pineapple in female hysteria.

Clinical Department.

REPORT OF TWO CASES OF ECTOPIC GESTATION; OPERATION ON ONE AT TERM, WITH DELIVERY OF LIVING CHILD, AND ON THE OTHER AT SIX WEEKS.*

BY T. N. RAFFERTY, M.D., AND H. N. RAFFERTY, M.D., ROBINSON, ILL.

FOR the early history and details of Case I we are indebted to Drs. C. H. Voorheis and J. B. Cato of Hutsonville, Ill.

CASE I.—Mrs. G. B., an American, forty years of age and housewife by occupation, had, until the beginning of her present trouble, always enjoyed good health, with the exception of the ordinary diseases of childhood. Menstruation began at the age of thirteen, and the periods were normal and regular up to the time of her first pregnancy. She is the mother of four children, the youngest being four years of age. Her labors have always been easy and normal. Her last regular menstruation began July 4, 1900, and lasted four or five days. On September 2d, at 4 o'clock A.M., Dr. Voorheis was called and found the patient in a state of collapse, with extreme pallor, vomiting, restlessness, and thirst, and suffering intense paroxysmal pain, radiating from the right iliac fossa, with abdominal tenderness. The Doctor failed to get a complete history of the case—as to cessation of menstruation, etc.—and consequently was in some doubt as to the diagnosis. The patient's condition was desperate, but under repeated hypodermatic stimulation and rest, she rallied. In October following there was a slight menstrual flow, with discharge of decidual remnants. From this time on there was a gradual enlargement of the abdomen. The woman was confined to her bed most of the time, and complained of indefinite pains, originating in the right hypochondrium. In December she first felt fœtal movements, and noticed that her breasts were enlarged and tender. From this time she had persistent vomiting, vesical and rectal tenesmus, and obstinate constipation. On April 4, 1901, one of the writers first saw Mrs. B. in consultation with Drs. Voorheis and Cato, and found her condition as follows: A woman prematurely aged by at least ten years, of a nervous temperament, extremely emaciated, with characteristic ovarian facies. The skin was sallow and slightly icteric—no doubt from external pressure on the common bile duct. The temperature was normal, pulse 120. Inspection of the patient in the recumbent position showed the abdomen to be as large as that of normal pregnancy at term, though its shape was rather that of ascites, and the enlargement was higher in the abdominal cavity than in ordinary pregnancy. On palpation the tumor was found to extend transversely across the abdomen, its greatest circumference being midway between the umbilicus and the tip of the ensiform cartilage. The tumor was most distinct in the two hypochondria; in the right, easily outlined, was a round solid mass, the size of a cocoanut, and slightly movable. The percussion note was dull over the entire abdomen, with the exception of a small area in the left flank. On auscultation a distinct pulsation, at the rate of 140 per minute, was heard at a point about four inches to the right of the median line, and two inches above a line drawn transversely through the umbilicus. No fœtal movements could be felt at this time, but they had been perceived by the mother that morning. The breasts are enlarged and pigmented. Vaginal examination showed a cervix large and soft, and a patulous os. A sound passed to a depth of three and one-half inches. The uterine corpus was somewhat enlarged, but empty. Neither ovary, tube, nor pelvic tumor of any sort could be outlined. By inserting a finger in the rectum and drawing down the cervix with a tenaculum the whole uterus could be easily outlined, and was found to have no immediate connection with the abdominal tumor.

A diagnosis was made of secondary abdominal pregnancy at term, with viable child, following a ruptured tubal gestation at the eighth week; child probably lying transversely in the peritoneal cavity, with head in the right hypochondrium, and elbow or knee presenting at the most prominent point of the abdomen. All present concurred in the diagnosis, and agreed that immediate laparotomy offered the only chance for mother as well as child. Accordingly, on April 6th, the patient having been prepared previously by a laxative, rectal enema, and bichloride dressing to the abdomen and flanks, a cœliotomy was done under chloroform anæsthesia. The incision was begun in the median line, at a point three inches above the umbilicus, and was extended downward and to the right in the direction of the anterior superior spine of the ileum, a distance of five inches. There was an excess of subcutaneous fat for one so emaciated, and the peritoneum was thick and leathery. The left elbow of the child presented in the wound as soon as the peritoneum was opened, this confirming the diagnosis of a transverse position. The child's back was turned toward the mother's diaphragm, the occiput pressing against the right lobe of the liver and the face looking downward. The child was turned so as to make a brow presentation, and delivered through the incision without difficulty. The cord was ligated and cut near the child, and again within four inches of its placental attachment. There was no sign of a fœtal sac, except for a few shreds of tissue—probably remains of the amnion—the child lying perfectly free in the abdominal cavity in front of the intestines. There was a small amount of fluid in the abdominal cavity, probably ascites from pressure. The placenta was unusually large and plethoric-appearing, being about 6 x 7 x 2 inches in size, with the cord attached near its upper margin. Its probable attachment was to the right tube and broad ligament, and the intestines posteriorly, but time was not taken to make this certain, owing to fears of uncontrollable hemorrhage. It being evident that any effort to remove the placenta would be disastrous, the upper end of the abdominal wound was closed with interrupted silkworm-gut sutures, but the lower end was left open, and through it was drawn the cut end of the cord, while iodoform gauze was packed above and around the placenta. During the operation the patient was given decinormal salt solution per rectum, and repeated hypodermics of strychnine and whiskey. The operation was bloodless. After the woman was returned to bed, heat was applied externally, and a pint of decinormal salt solution was given subcutaneously. The pulse was 140 at the close of the operation. The patient rallied well from the anæsthetic, suffered but little shock, and did not vomit during the day. The child, a male weighing eight and one-half pounds, seemed in fairly good condition, though it was somewhat cyanotic. On April 7th, twenty-four hours after the operation, the woman's temperature was 99°, pulse 135, but fairly good. She had vomited once after taking hot milk. The bowels and bladder had moved without aid. The child died at midnight, cyanotic, having lived thirteen and one-half hours. On April 8th, at 8 A.M., or forty-eight hours after the operation, the woman's temperature was 100°, pulse 135. The wound was redressed. The

*Read before the Æsculapian Medical Society at Mattoon, Ill., May 16, 1901, and published by request.

packing was slightly soiled at one point with clear fluid, but there was no sign of any hemorrhage. The placenta seemed slightly shriveled. Its surface was mopped off with gauze wrung out of sterile saline solution, and the wound was repacked. At 6 P.M. of the same day, the temperature was 99°, pulse 135, no vomiting. Nutrient enemata were given during the day. April 9th, the temperature was normal, pulse 130. The patient was thirsty and very hungry—condition promising. April 11th, at 8 A.M., the temperature was 102°, pulse 135, there had been some cough during the night. The dressing was changed, and a loop of intestine slightly adherent, was found in the wound. There was no change in the appearance of the placenta. The patient's expression was anxious. At 6 P.M. her temperature was 103°, pulse 150; the wound was dressed, and the peritoneal cavity was irrigated with sterile salt solution at a temperature of 105° F., and two quarts of the same solution left in the cavity. The patient's condition gradually grew worse, and death occurred at 3 A.M., April 12th, on the sixth day after operation.

The autopsy was made seven and one-half hours after death. Rigor mortis was incomplete. The abdominal wound, where united by sutures, was fairly firm, with no sign of pus in either the wound or the stitch-holes. The abdominal wound was enlarged from sternum to pubes. The placenta filled the brim of the pelvis, and was firm and full of blood. It was situated in the median line, attached in the middle of the lower end to the fundus uteri, on the left side to the broad ligament and to the sigmoid flexure of the colon and its mesentery, so firmly that separation was impossible, except at the expense of the placenta. The left tube and fimbriated extremity were of normal size and free from adhesions; the lumen of the tube was patulous to within an inch of the horn of the uterus, at which point a small probe could not be passed. The left ovary, the size of a small prune, was in its normal position, and showed no sign of cystic degeneration nor a corpus luteum. On the right side, the placenta had retained its original attachment to the tube, showing the rupture to have been at the junction of the middle and outer thirds of the tube. The right broad ligament and ovary were fused into one unrecognizable mass of adhesions. There were also numerous but less firm adhesions to the small intestines on the right side. The omentum was long, thick, and vascular, but entirely free from adhesions. The uterus occupied its normal position, and was symmetrically enlarged and firm. The uterine muscle was hypertrophied and healthy in appearance. Externally the uterus measured four and one-half inches in length, by two and one-half inches in width, through its body. The cavity was empty. The cervix was soft and patulous. There was no sign of fœtal membranes, except for a thick adherent capsule covering a portion of the placenta, which might be considered as remains of the bursted amnion.

Case II.—Mrs. K. S., an American housewife, thirty-three years of age. There is no history of any previous illness, except indigestion. She first menstruated at the age of fifteen, her menstrual periods having always been regular, and usually painless. She was married at twenty-two, giving birth to a male child a year later. Since then her menses have been normal, but she has had more or less leucorrhœal discharge. She has never had a miscarriage. She last menstruated during the fourth week in February of the present year. On April 9, she worked in the garden and further exerted herself by lifting down a heavy weight from above her head. On the morning of April 10, while sweeping, she was suddenly seized with a sharp lancinating pain in the left iliac region, radiating over the abdomen, and accompanied by faintness, partial blindness, and thirst. Her family physician, Dr. A. G. Meserve, was called, and found her pulseless and cold, with lips and gums pale, and all indications of acute anæmia from internal hemorrhage. After making a hurried examination, and getting a history of the missed menstrual period, Dr. Meserve made a provisional diagnosis of extra-uterine gestation, with rupture and hemorrhage. Under careful stimulation the patient rallied somewhat, her pulse at times becoming much better, only to sink again away from the finger with renewed bleeding. On the day following, Mrs. S. was seen by us in consultation with her attending physician, to consider the advisability of surgical interference. At this time her condition was as follows: pulse 120, temperature 99°, lips and gums bloodless. She complained of no pain, but vomited occasionally. The abdomen was tender and tympanitic; the bowels were constipated. Vaginal and rectal examination failed to show the presence of any pelvic tumor. The broad ligament on each side seemed thickened somewhat, and the left ovary was enlarged. The uterus was slightly enlarged. There was no fluctuation in Douglas' pouch. As we could not get the family's full consent for operative intervention, it was deemed best to await developments.

On April 13, her general condition being less favorable than on the preceding day, a laparotomy was consented to. Under ether anæsthesia, the peritoneum was opened, and dark semi-fluid and clotted blood at once appeared in the incision. It having been first ascertained that there was no active bleeding, and that the rupture had occurred in the left tube, the ovarian and uterine arteries were ligated, and the tube and ovary were removed. The rupture in the tube had occurred about three-quarters of an inch from the uterus, and in order to get a suitable stump, a suture-ligature was passed through the muscle wall of the uterine horn, and the cut end of the stump was inverted with several Lembert sutures. The ovary contained a cyst as large as a hen's egg, and was completely buried in a mass of old adhesions in the broad ligament. A small portion of normal ovarian stroma remained, and showed a corpus luteum. The bursted tube—the erstwhile resting place of a misguided embryo—was gaping widely, with no vestige of a clot, the only barrier against hemorrhage being the low arterial tension—rather uncertain at the best. The right ovary was likewise adherent, but it was not deemed advisable to prolong the operation by a further inspection. The uterus seemed to be as large as one in the second month of pregnancy. The pelvis was cleansed of clots, as were the intestines and adjacent organs, by mopping with gauze sponges wet with hot sterile salt solution. While we were thus occupied, the six weeks' ovum was found free in the pelvic cavity among the blood clots. The abdominal walls were closed with through-and-through sutures of silk-worm gut. The patient rallied well from the anæsthetic, and until the tenth day her recovery was uneventful. At this time there was a slight rise in temperature, which continued for several days, due to the development of several stitch-hole abscesses, and a mild sapræmia from the retained decidua. Following the operation for several days there was, as usual, a slight sanguineous discharge from the uterus. On April 27, or fourteen days after the operation, there was a sudden gush of blood from the uterus followed by the discharge of shreds of decidual membrane, partly decomposed.

Shreds of membrane continued to pass for several days. Curettage was probably indicated, but was not done.

It has occurred to us that these cases deserve attention for several reasons. The patients were both operated on within a week, in country homes, within fifteen miles of each other, and each time in consultation with a member (or members) of the Æsculapian Society.

From the statistics to which we have had access, and which include the period from 1809 to 1896, or eighty-seven years, it is learned that seventy-seven ectopic viable fœtuses have been delivered by cœliotomy. Six of these only have been reported by American surgeons—the remainder by Europeans. Of the seventy-seven cases so reported, thirty-seven were operated on during the first eighty years of this period, with nine maternal recoveries; while in the forty cases reported during the last seven years of the period, there were twenty-seven maternal recoveries. The fœtuses thus delivered have lived for periods varying from a few minutes to several years. These statistics have been obtained principally from the table given in Kelly's "Operative Gynecology" and from a private communication from Dr. E. P. Davis, Professor of Obstetrics in Jefferson Medical College, of Philadelphia.

In a table given by Werder, there are records of three maternal recoveries in cases in which a viable fœtus was lying free among the intestines, without a sac. The present case, so far as we have been able to determine, is the first to be reported in this country in which a cœliotomy has been done with a viable ectopic fœtus without a sac.

Abdominal section at the time of an early ruptured tubal gestation has become common since the perfection of modern technique, but the case just cited has been given space chiefly for the purpose of comparison. These two cases serve as examples of extremes: of the castaway embryo of six weeks and the viable fœtus at term; of recovery and of death, the alpha and omega of ectopic gestation.

The specimens and their histories are silent witnesses of the indications for treatment in such cases. They cannot prevaricate or mislead, as the living patient too often is inclined to do. They mutely testify that, in the second case, the grim reaper was foiled, and that he could and should have been in the first, had the same methods been employed at a corresponding time. It is again the "handwriting on the wall," and we trust so plain and indelible, that "he who runs may read."

SURGICAL TREATMENT OF ASCITES, DUE TO CIRRHOSIS OF THE LIVER; REPORT OF A CASE.

By JULIUS H. JACOBSON, M.D.,
TOLEDO, OHIO
LECTURER ON PHYSICAL DIAGNOSIS, TOLEDO MEDICAL COLLEGE; ATTENDING SURGEON LUCAS COUNTY INFIRMARY HOSPITAL

On June 5, 1901, C. B., age forty-five, laborer, was admitted to the Lucas County Infirmary Hospital. His history was as follows: Family history, negative; when a child he had measles, parotitis, and scarlatina, during which latter affection otitis media developed, leaving him quite deaf; he denies having had syphilis, but he had gonorrhœa ten years ago; he has used alcohol in large quantities, both beer and whiskey; he had several attacks of renal colic about six years ago, and has passed some stones through the urethra.

Concerning his present illness, the patient stated that during the fall of 1900 he first began complaining of distress in his stomach after eating, with more or less pain in the region of the stomach, headache, and severe diarrhœa. This diarrhœa continued until the spring of 1901; the discharges were at times mixed with blood. About April 25, 1901, the patient first noticed some swelling of the feet. This progressed rapidly, extending up the entire lower extremities; the abdomen then became swollen and enlarged to a considerable size. Under treatment this disappeared for a time, but reappeared later. He had no jaundice; the appetite was not good.

The patient is a well-developed individual, presenting no emaciation; pulse 80, and full but regular; temperature normal. There is œdema of the lower extremities, and the abdomen is enlarged. The lungs are normal; the heart area is increased to the left; the cardiac sounds are irregular, but clear; there are no enlarged veins over the abdomen, but it is distended with signs of fluid. On palpation, the liver can be felt about three finger-breadths below the costal margin, and is hard and firm. The spleen is not palpable. There is a small umbilical hernia. The urine on first examinations was normal, but later a small quantity of albumin was found.

A diagnosis was made of cirrhosis of the liver. The patient was treated with diuretics and cathartics, as a result of which the ascites and œdema gradually disappeared, so that the patient left the hospital in ten days. He re-entered the hospital June 25, 1901, when, on examination, the abdomen was again found distended with fluid.

The operation of anastomosing the portal with the systemic veins by suturing the omentum to the parietal peritoneum was decided upon. I performed the operation June 28, 1901, assisted by Dr. Lyman A. Brewer of this city. General anæsthesia was employed, beginning with chloroform and continuing with ether. An incision, about four inches long, was made in the median line above the umbilicus, extending downward a little to the right. When the peritoneal cavity was opened a quantity of ascitic fluid escaped. An attempt to evacuate the fluid by turning the patient over on his right side was unsuccessful. As much as possible of the fluid was removed by gauze sponges, though the greater part still remained. Exploration of the abdomen verified the diagnosis of cirrhosis of the liver, that organ being found greatly enlarged, hard, firm, and roughened on its under surface, extending below the costal margin for about the distance of five finger-breadths.

The peritoneum on either side of the incision for a distance laterally of about three inches was vigorously rubbed with gauze pads and then scarified. The omentum was then stitched to the parietal peritoneum, on both sides of the incision, by a continuous catgut suture. The abdomen was closed with interrupted silkworm-gut sutures, some of the omentum being included in the bottom of the wound. During the operation the patient did not take the anæsthetic well, requiring repeated stimulation.

On examination twenty-four hours after the operation, the œdema and ascites were found to have entirely disappeared. The man did very well until the evening of the sixth day, when he became comatose, and died the following day, seven days after the operation, the cause of the death being evidently uræmia. Repeated stimulation with strychnine, venesection followed by intravenous transfusion with salt solutions, together with subcutaneous injection of salt solutions, were resorted to, but with no effect.

Post-mortem examination revealed the following: At the site of the operation there was complete adhesion of the omentum to the abdominal wall. The left ventricle of the heart was hypertrophied; there was a typical cirrhotic liver, the spleen was congested; the left kidney was contracted and contained two small stones; the right kidney was contracted yet larger than the left one; the right ureter was thick-

ened and enlarged, and contained an impacted stone near the vesical orifice.

The two chief points of interest in this case were:

1. The rapid disappearance of the ascites and œdema after the operation. One week was too short a time for vascular adhesions to form between the omentum and peritoneum, for it requires a much longer period for such an anastomosis to form. In a number of the cases, thus far reported, tapping was resorted to several weeks after the operation, in order to remove what fluid had accumulated before vascular anastomosis had taken place. The rapid disappearance of the fluid in this case cannot be explained in this manner. Just how the absorption took place I am unable to say, but am inclined to the belief that the extensive scarification of the omentum and peritoneum was an important factor in its disappearance, as thereby these structures were enabled to take up and absorb the fluid more readily.

2. The patient did not die as a result of the operation, but from uræmia due to the contracted kidneys.

So far comparatively few operations for the relief of ascites and œdema following cirrhosis of the liver have been made, and no definite estimate of the value of this procedure has been formed; nor has its exact place as a rational operation been definitely fixed.

The anastomosis of the portal veins with the systemic veins, by the creation of vascular adhesions between the omentum and peritoneum, theoretically gives brilliant prospects of relief in this incurable condition. In a number of the cases thus far reported the results have been encouraging. It seems highly probable that, were the operation performed earlier in the course of the disease, *i. e.* before secondary involvement of other organs has taken place, much better results would be obtained.

BELLADONNA IN OBSTRUCTION OF THE BOWELS.

By JOHN W. S. McCULLOUGH, M.D.,
ALLISTON, ONT.

In April last, I was called a distance of some thirty miles, with the request that I come prepared to do an abdominal operation. Upon my arrival at midnight I found the patient, a spare Highlander, seventy-five years of age, with tortuous arteries, suffering from fæcal obstruction, in which condition he had been for eight days, despite the frequent use of purgatives, enemata, etc. The abdomen was very much distended, the coils of intestine being plainly visible through the shining walls of the belly. The pulse was 92, the temperature normal.

Recognizing that the condition of the patient was not a very favorable one for operation, I determined to try the effect of a plan of treatment I had read of from the pen of Dr. Murray of Newcastle, England, in his excellent little brochure entitled "Rough Notes on Remedies." The patient was placed upon tincture of belladonna (B. P.) ♏xxx, hourly. This was continued for six doses and then supplemented by an enema of ox-gall, one ounce in a quart of soap suds. The effect was negative. As the doses of belladonna had given the patient relief from the intense pain he suffered, and had so far produced little physiological effect, the dose was increased to ♏xl, every hour for four doses, and followed by a high enema, this time of magnesium sulphate and turpentine in warm water. There was very little of the desired effect and in two hours the belladonna was administered again and supplemented by an abdominal plaster, 20 inches square, of

℞ Ung iodi (B. P.) ..... ℥i.
Ext. bellad. (B. P.) ..... ʒi.

This produced the characteristic effect of belladonna poisoning, viz., intense dryness of the throat, redness of the face and body, and delirium. This plan of treatment was kept up, having been begun about midnight of Monday until the following Friday afternoon when peristalsis was vigorously established, and the bowels moved freely. The patient thenceforward progressed to complete recovery.

In the *British Medical Journal* of May 11th last, a similar case is recorded, the treatment having been carried out by means of hypodermic injections of atropine in doses of $\frac{1}{100}$ to $\frac{1}{50}$ grain. This would, of course, be the better plan in case the patient had vomiting and could not retain the belladonna given by the mouth; or suppositories containing the drug might be given. In either case, the use of the abdominal plaster will prove of decided assistance, the irritation produced by the iodine accelerating very materially the absorption of the belladonna.

I am convinced that the treatment saved this patient's life, as he was in such condition that operation would have been most hazardous. If the drug is given cautiously at first, the patient being watched carefully, there need be no apprehension of overdosage.

DERMOID TUMOR OF THE LUNG.

By H. OTTO SOMMERS, M.D.,
WASHINGTON, D. C.
LATE OF HOUSE STAFF AND ASSISTANT PATHOLOGIST METROPOLITAN HOSPITAL, NEW YORK.

At an autopsy held March 1, 1898 (hitherto unpublished), I met with a dermoid tumor of the lung. The patient, a man aged twenty-seven years, died of phthisis pulmonalis chronica. Both lungs were markedly tuberculous and cavernous. At the apex of the right lung was found a cystoid body, containing large masses of hairs and some dentoid bodies. Dermoids of the lung are very rare, but those who are inclined to be skeptical as to their existence, I would refer to Ziegler's Pathology, which recognizes the condition, and cites Agle on "Dermoid Growth of Lung," in the Transactions of the Pathological Society of London, XVIII., 1897; and also Jares on "Dermoidcyste mit Cystosarkom der Lunge," in Virchow's *Archiv*, 133 Bd., 1879.

1227 O STREET, N. W.

Tuberculosis Herniosa.—F. Justian contributes the twenty-ninth case of this rare lesion which has been reported in detail in the literature. The patient was a man of twenty-two who applied for relief from a right inguinal hernia of two weeks' standing. Physical examination revealed that, in addition to his abdominal condition, he was suffering from a pleurisy with exudation on the left side, which was treated by aspiration, but as the temperature still continued high, empyema was suspected, and a thoracotomy performed. No pus was found, but the temperature subsided, and after it had been flat for two months herniotomy was done. The sac was greatly thickened, and contained a considerable quantity of clear fluid, on the removal of which it was seen that the surfaces of the sac and of a coil of intestine were thickly studded with miliary tubercles. The sac was resected as high up as possible and the operation concluded as usual after Bassini's method. The wound closed by first intention, though for a week there was a slight evening rise of temperature. At the time of the report the patient appeared to have entirely recovered. The infection of the hernial sac seems to have been secondary to that of the pleura and a probable latent tuberculous peritonitis, while no signs of it could be found in the lungs or other organs.—[Abstr.] *Zeitschrift fur Chirurgie.*

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Sixty-fourth Regular Meeting, Held on Friday, May 3, 1901.

A. ALEXANDER SMITH, M.D., PRESIDENT, IN THE CHAIR.

Recurrent Mammary Cancer—Retrograde Metamorphosis After Oöphorectomy.—DR ROBERT ABBE reported two cases. The first patient was a woman of forty-two years, who had a bad mammary cancer removed with axillary contents by Dr Coe, in May, one year ago. Six months after, recurrence took place about the scar. She delayed seeking advice until a secondary tumor appeared in the other breast and grew to the size of a small hen's egg. Dr. Coe then regarded operation as wholly unjustified, and soon she came to Dr Abbe to have another opinion. Her condition was absolutely hopeless from an operative point of view.

There was an area of carcinoma nodules, varying in size from a pea to a large bean, on both sides and in the scar, covering an area two and one-half inches on one side and three inches on the other side of the scar, and spreading from the axilla to the lower end. The masses ran together in places and were somewhat fixed to the ribs and intercostal muscles. The infected area was typical of carcinoma cuirass and measured four inches by seven inches, the scar running diagonally through it, and being fixed to the chest. In the opposite breast was a typical hard scirrhous growth in the outer segment the size of an egg. Near it, and extending to the axilla, were several glands, in chain.

The left chest presented a cancerous pleurisy with five inches of fluid and dull pleura above the fluid, which seemed the clinical picture of a secondary carcinomatous pleuritis.

Dr. Abbe removed both ovaries March 4th, with tubes. Both were full size and appeared normal, except that the left (on the side of original cancer) was lightly adherent to the adjacent pelvic peritoneum. The pathologist reported both as normal. She menstruated for two days after operation for the last time, it being at one of her regular periods, which previously had been always right. She had never been married.

Convalescence was perfect, and we watched the diseased parts carefully. About ten days after operation the heaped-up nodules began to flatten. Some even hollowed out their round tops. In the following week every one went through the same retrograde change, and most of them were umbilicated, presenting a ring of neoplasm, and losing the red, active hyperæmia existing before.

In four weeks the opposite breast tumor was shrinking. In six weeks it was gone. The whole infected area was now represented by dusky pits, where each cancer mass had been, and there remained only one or two vanishing nodes at the upper end of the scar, and two or three disappearing lymphatics in the opposite axilla.

The pleurisy subsided with equally surprising result, and the dulness of the underlying pleura gave a more and more resonant percussion note. The pleurisy had not wholly gone at seven weeks, but every trace of malignant disease had, excepting only two small glands in the right axilla. No other medicine was given, and the patient has maintained excellent health, resuming her duty as trained nurse five weeks after operation.

The second case was one of recurrent cancer of the left breast, two years after the original operation by himself. Three independent round masses, from one-quarter to one-half inch in diameter, with five or six nearby subcutaneous ones were distributed within an area of three inches at the lower end of the scar, while on the scar itself was an ulcer three-quarters of an inch in diameter, resting on the intercostal pleura, with heaped-up edges. It would have been impossible to remove it without entering the pleural cavity. The patient was fifty-nine years old, and had ceased menstruation, therefore a questionable case to hope for retrograde change; yet the chance was given. Both ovaries were extremely atrophied and removed. Convalescence was uneventful. On the eighteenth day the report was as follows: During the past week the ulcer has markedly changed. The edges first began to flatten and the center to fill. The granulations were of less deep color and have changed to a good pink. The edges are quite flat around two-thirds, and the skin is healing in, through about one-third of the circumference. The nodules have all become less hyperæmic, and one is now quite umbilicated, already showing the changes which the other case presented. The subcutaneous small nodes are all less perceptible. No other treatment has been given.

DR GEORGE L. PEABODY said the evidences of local improvement in the two cases shown by Dr. Abbe were very striking. There was nothing in the appearance of the parts at present to suggest carcinoma. The induration had entirely disappeared, leaving only pigmented patches.

Dr. E. G. JANEWAY said the second patient shown by Dr. Abbe was fifty-nine years of age, and it was questionable whether the ovaries could exert much influence upon the breasts at such an advanced period of life, after menstruation had ceased. It would be interesting to watch the future course of these patients and see whether the improvement will be permanent. It would also be interesting to learn whether there are cases on record where carcinoma of the breast has occurred after a woman has been deprived of her ovaries. Dr. Janeway asked Dr. Abbe whether oöphorectomy had ever been done for primary carcinoma of the breast, or only after a recurrence of the disease.

Dr. Abbe replied that it had been done a few times in connection with the removal of the affected breast. He said also that while cancer of the male breast is occasionally met with, many of the cases reported as such are very late lesions of syphilis.

Dr. H. F. WALKER said it was rather difficult to believe that the removal of the ovaries in a woman nearly sixty, after those organs had become practically atrophied, could exert much influence upon the growth of a mammary cancer. The fact should also be borne in mind that malignant disease of the breast is comparatively rare in young women, during that period of life when the ovaries are most active.

Dr. JOSEPH D. BRYANT said that he had been watching for some time the literature in connection with this subject, but this was the first opportunity he had enjoyed of seeing any of the cases in which the operation had been resorted to. The first case shown by Dr. Abbe impressed him very favorably, but in the second case, that of a woman almost sixty years old, it was hardly credible that the removal of her ovaries could exert much effect upon a malignant growth of the breast. It not infrequently happens that such growths disappear spontaneously: instances of this had come under his observation, where no cause could be assigned for the disappearance of the cancer. If we accept the theory that removal of the ovaries exerts a curative influence in cancer, it surrounds the question of the etiology of that disease with still greater difficulties.

Dr BEVERLEY ROBINSON said that at a meeting of the Practitioners' Society about two years ago he reported the case of an elderly woman with a carcinoma of the breast which after two recurrences was pronounced inoperable. There was extensive infiltration and swelling of the arm on the affected side, with much pain. Various drugs were resorted to, and she finally improved considerably under one of the quinine compounds that had recently been put on the market. For some weeks previous to her death, which was due to an extension of

the cancerous process to the lung, the infiltration of the tissues of the arm had entirely disappeared, and she was free from pain. Dr. Robinson said he agreed with Dr. Bryant that if the removal of the ovaries proved efficacious as a means of curing cancer of the breast, it would probably upset all the latest theories that have been evolved regarding the etiology of malignant disease. Personally, Dr. Robinson said, he could not conceive how the removal of a set of organs like the ovaries could have any permanent effect upon the growth of a mammary cancer.

Dr. Abbe, in closing, said that the improvement in the two cases he had shown was marvelous, and unequaled by anything he had ever seen. The speaker said he had no claims to advance regarding the permanent value of this method of treatment, and he simply showed the cases for their remarkable clinical interest. This method of treatment of inoperable recurrent mammary cancer was first suggested by Mr. Beatson, a Glasgow surgeon, who had been led to resort to it by a process of reasoning which was the outcome of an observation that certain farmers had indefinitely prolonged lactation in their cows by spaying them when they had begun to cease giving milk. In explaining this phenomenon he thought it probable that the suspended menstrual function during lactation and the continued giving of milk on removal of the ovaries might be of similar causation. The production of milk is physiologically due to rapid development of cells lining the tubules and acini of the mammary gland, which undergo fatty degeneration, break their capsules, and discharge fat globules in the form of milk. Restoration of ovarian function and arrest of milk-giving occur at the same time, but the removal of the ovaries causes the continued degeneration of these rapidly growing cells. If cancer of the breast, he argued, is a proliferation of the cells lining the acini and tubules, from whatever unknown cause, making a massive growth, discharging into nearby lymph channels and being arrested in the lymphatic glands, why might not removal of the ovaries produce a retrograde metamorphosis also in these same cells, as they are identical with those which yield milk?

His first case was quite as remarkable as the one first exhibited. The method has been adopted in fifty or more cases already reported, and occasionally yields a cure in hopeless cases, even after several recurrences. The outlying nodules and infected lymph glands as well as metastatic growths seem to show this same retrograde degeneration and melt away, day by day, very much as a syphilitic tumor degenerates.

About thirty-five per cent. of reported cases show a striking improvement, and in some the cure was almost magical and has lasted. Dr. Abbe said that in the first case which he had shown, an improvement in the cancerous breast was noticed within ten days after the removal of the woman's ovaries. There was a distinct loss of hyperæmia, then the lesions became flat, then umbilicated, and finally disappeared, leaving only a shallow thin soft scar. It was a typical process of retrograde metamorphosis.

An analysis of the cases reported by English surgeons shows that the results were not as good in those patients who were operated on after the menopause as in those operated on earlier in life. Yet some as old as seventy years were cured. Dr. Abbe's second patient is seventy years old and is progressing to a cure in the same orderly way as the first. (P. S.—The cancer ulceration was entirely healed on the fortieth day, and the nodules are retrograding rapidly.)

Various Interesting Intestinal Anastomoses. — Dr. ROBERT ABBE presented five patients. The first patient was a man, fifty years old, who was operated on about six years ago. He was at that time suffering from indefinite intra-abdominal symptoms which were at first attributed to gall-stones and later to malignant disease. He was cachectic and had lost thirty pounds in weight. After a trip to Egypt, where he failed to recover his health, he entered St. Luke's Hospital, and an exploratory operation was done by Dr. Abbe. The gall-bladder contained no gall-stones. The head of the pancreas was much enlarged and very hard to the touch, and a long, round needle was passed into it in several directions to detect a possible calculus or gall-stone, but the growth was of the consistency of a raw potato and regarded as probably malignant. By means of a Murphy button the gall-bladder was anastomosed to the duodenum near the head of the pancreas and the wound was closed. The patient made a rapid recovery after the operation, soon regained his lost weight, and has since enjoyed perfect health. The Murphy button was passed in twelve days. The hard mass involving the head of the pancreas, which was regarded as malignant, was probably of inflammatory origin. Chronic pancreatitis has recently been shown to be due to dammed-back bile entering the pancreatic duct and acting as an irritant to that gland, the original obstruction being a small gall-stone.

The second patient shown by Dr. Abbe was a young man who was suffering from malignant disease of the stomach, which had greatly emaciated him during the past year. About two months ago Dr. Abbe did a posterior gastroenterostomy, and found the right half of the stomach densely infiltrated with cancer while the left half was comparatively healthy. In order to relieve the man's symptoms, the jejunum was anastomosed to the posterior wall of the stomach, which was in a healthy condition. The anastomosis was done with the Murphy button, which was passed on the eleventh day. Since the operation the man has gained about a pound a day.

The third patient presented was a man who, five years ago, developed symptoms of intestinal obstruction, which were gradually becoming more aggravated, and were accompanied by great loss of flesh and strength. Palpation disclosed a hard mass to the right of the umbilicus. It was regarded as probably malignant. Upon opening the abdomen the tumor was found to be composed of conglomerate coils of small intestine, together with glands in the mesentery. About eighteen inches of the gut were involved in this tangled mass, and upon close inspection it was found to contain six tight strictures. The mass was isolated and cut away. The two ends of the intestine were brought together by an end-to-end anastomosis with Murphy's button. The patient made a rapid recovery and has enjoyed perfect health ever since.

A pathological examination of the mass removed showed that it was a simple cicatricial stenosis, probably due to an ulcerative process. There were no signs of malignancy.

The fourth patient was a man whose general health had been running down for six or eight months when he came under Dr. Abbe's observation six weeks ago at St. Luke's Hospital. He stated that his abdomen had rapidly grown larger and that he was becoming more and more exhausted. Upon examination no mass could be made out in the abdomen, but there was huge distention of the intestines. A left inguinal colotomy was immediately done, and gallons of thin fluid fæces were evacuated, following which a median incision revealed in the sigmoid, just above the rectum, a symmetrical tumor, about the size of a walnut, evidently an epithelioma. The patient was allowed to recuperate for ten days; then the abdominal wound was reopened, and four inches of the sigmoid, including the tumor, removed. The two ends of the gut were united with a large Murphy's button, which was passed in two weeks. Since the operation, the patient has gained rapidly in weight and strength. The colotomy wound closed immediately when inverted, and the patient now enjoys excellent health.

To complete the group Dr. Abbe then presented the following case of intestinal anastomosis: The patient was a man who for ten years had suffered from pain which

always occurred several hours after taking food. He was seen by Dr. Osler ten years ago, who pronounced the case one of pyloric stenosis of cicatricial origin. The stomach was much distended, extending down below the navel, and showing plainly in the retracted abdomen. The patient had lost much weight, but there were no evidences of malignant disease.

Four weeks ago, when Dr. Abbe opened the abdomen, he found the pyloric orifice constricted. There was no hardness of the tissues, but evidence of internal cicatrix was shown by a thick layer of old lymph on the front of the pylorus. An anastomosis was made with a Murphy button between the jejunum and the posterior wall of the stomach. For two weeks after operation the patient has been gaining in weight one pound daily and has been able to enjoy many articles of diet, especially starches, which he was compelled to abstain from during the past ten years.

Dr. Janeway said the case of supposed carcinoma of the head of the pancreas reported by Dr. Abbe reminded him of a similar case which came under his observation some years ago. The patient was a woman who complained of vague abdominal symptoms, and an exploratory operation revealed a mass involving the head of the pancreas. It was regarded as an inoperable case of cancer of the pancreas, and the wound was closed. Soon after the operation, however, her symptoms improved, and eventually she entirely recovered. As in Dr. Abbe's case, there was perhaps an over-distention of the head of the pancreas, due to closure of the duct, which was relieved by the operation, or possibly some inflammatory condition.

In regard to the third patient shown by Dr. Abbe, Dr. Janeway said the multiple strictures of the gut in that case were possibly of syphilitic origin. Such cases have been reported, and it was difficult to explain their presence upon any other basis. Such strictures are not apt to occur after typhoid.

Dr. Abbe, in reply to a question, said he had never seen bile regurgitate into the stomach after an anastomosis between the gall-bladder and duodenum. In anastomosing the stomach and jejunum, the speaker said he had in only one instance reversed the coil, so as to bring the peristaltic wave of the stomach and intestine in the same direction. When the peristaltic wave of the stomach goes in one direction and that of the jejunum in the other, the anastomosis seems to be just as satisfactory.

Renal Calculi, with Radiographs and Specimens.—Dr. Abbe showed seven renal calculi which he had removed after the stones were located by means of the *x*-ray. All patients recovered. In connection with these cases, the speaker emphasized the importance of conservative surgery in the treatment of stone in the kidney. Even in cases where suppuration has occurred and the organ is much atrophied, its function will be restored if the source of the irritation is removed. The urinary sinus usually persists for months, but when the incision is made through the kidney substance and not through its pelvis, the sinus always heals.

Dr. Janeway said that the use of the *x*-ray in the diagnosis of cases of renal calculi had led some surgeons to operate in cases where the kidney or ureter contained very small stones—much smaller than are frequently passed spontaneously.

Three Cases of Meningitis with Bacteriological Diagnosis During Life.—Dr. F. P. Kinnicutt reported these cases. The patients, two adults and one child, were under observation at the same time at the Presbyterian Hospital. In two of the cases the clinical symptoms were characteristic of cerebral meningitis with involvement of the spinal meninges, while in the third the symptoms were chiefly cerebral. In order to determine the specific form of meningitis from which these patients were suffering, lumbar puncture was resorted to. In all three instances spinal fluid was easily obtained. The specimen from the first case showed the pneumococcus in pure culture; in the second case it showed the diplococcus intracellularis; while the third specimen proved sterile. The first patient did not seem seriously ill on admission, but after the demonstration of the pneumococcus in the cerebrospinal fluid a bad prognosis was given. This proved correct, as the patient died on the sixth day after admission to the hospital. The autopsy showed a very severe form of cerebrospinal meningitis.

In the second case the prognosis was not considered to be as grave, although the patient was desperately ill. He lay in a state of complete coma for ten days, but eventually recovered. The third case, in which cultures of the cerebrospinal fluid proved sterile, was regarded as tuberculous. The patient died, and the autopsy confirmed the diagnosis of tuberculous meningitis.

Dr. Kinnicutt said that the consensus of clinical experience is to the effect that meningitis either of pneumococcus origin or due to the tubercle bacillus is fatal. On the other hand, the prognosis in cases of meningitis (cerebral and spinal) due to the diplococcus intracellularis is much less grave.

In the interesting group of cases reported, a diagnosis of the form of meningitis present was impossible except by bacteriological investigation and upon the results the prognosis was also based.

The result of lumbar puncture in cases of tuberculous meningitis Dr. Kinnicutt had found often to be of benefit in ameliorating symptoms, and in cerebrospinal meningitis due to the diplococcus intracellularis a distinct and beneficial effect upon the course of the disease had been claimed.

Dr. Robinson said that while the value of lumbar puncture in certain instances was beyond question, the procedure is not without danger. The speaker said he knew of one instance where the patient died within a few minutes after this apparently simple operation. The case was regarded as one of endemic or epidemic cerebrospinal meningitis, and the puncture was made for the purpose of establishing the diagnosis.

Dr. Kinnicutt said that in the very many cases of lumbar puncture that had come under his personal observation, he had never seen any resulting injury.

A Case of Carcinoma of the Distal Extremity of the Vermiform Appendix, with Specimen.—Dr. Charles McBurney reported this case. The patient was a woman twenty-three years old, who gave a history of having had an attack of what was clearly appendicitis about two years before she came under the speaker's observation. This attack was evidently a severe one, with a temperature as high as 105° F., but after about ten days the symptoms slowly subsided, and the patient remained well with the exception of a feeling of pain and discomfort in the right iliac region when she made certain movements, or took active exercise. About two months ago, however, pain in the region of the appendix became much more pronounced, and soon grew so severe that it entirely prevented the patient's usual activity. No rise of temperature or pulse occurred.

When Dr. McBurney saw the patient, her general health was apparently very good. She had no fever. An examination showed a very sensitive appendix, and an operation was undertaken for its removal. It was found to be about four inches long, and was greatly thickened and enlarged, but there were no attachments in the form of adhesions and no disturbance of the peritoneal surface of the appendix. After removal of the appendix it was found to contain two strictures, one near its base, the other near its apex. Near the apex was a small tumor, about the size of a green pea, quite solid and white in appearance on section. It was sent to Dr. Hodenpyl for examination, and he reported that it was a pure carcinoma. It was doubtless primary,

as the patient gave no symptoms of malignant disease elsewhere in the body.

Dr. McBurney said this was the first case of primary carcinoma of the appendix that had ever come under his observation. Through Dr. Hodenpyl, however, he was able to secure a second specimen of the same kind, which was removed post-mortem by Dr. Lartigau from a man about thirty years old, who had given no history of appendicitis. At the apex of his appendix a rounded tumor was found. It was considerably larger than the one found in Dr. McBurney's case, and an examination showed that it was pure carcinoma. The microscopical appearance of both was remarkably similar.

Dr. McBurney said that quite a number of cases of carcinoma of the appendix have been reported, but they were all, so far as he knew, cases where the disease was more or less extensive and the appendix was involved together with other organs.

Dr. PEABODY said there was no reason why carcinoma should not occur primarily in the appendix, although it was certainly rare in that situation. It was rather curious, however, that a young woman of twenty-three should be affected with the disease.

Dr. KINNICUTT said that another interesting feature of the case was the constant pain in the right iliac fossa from which the patient had suffered during the past two years, and from which she had been entirely relieved by the operation. The organ was free from any adhesions, and the only explanation he could offer for the pain was the presence of the two strictures, with perhaps the retention of secretions.

Dr. ROBINSON said he had long been waiting for a case which might be termed typical of gouty appendicitis, and during the past winter what he regarded as such a case had come under his observation. The patient had long suffered from a skin trouble which was of a gouty nature, and in addition to this he had recurrent attacks of pain in the region of the appendix. The appendix was removed by Dr. W. T. Bull, and found to be the seat of a catarrhal inflammation, similar to that met with in the tonsils, ovaries, and elsewhere, particularly in gouty individuals. Ultimately, Dr. Robinson said, we may reach the conclusion that organs like the tonsils and appendix have some valuable function to perform and that they should not be removed with too great freedom.

Dr. McBurney said that pain is complained of in a fair number of cases of chronic appendicitis, and is probably due to the presence of strictures, with the consequent retention of material, and also perhaps to the inflammatory thickening. The speaker said the case he had reported was a good example of the advantage of removing the appendix with as little delay as possible when that organ is suspected of being the seat of disease. In the case under discussion it is extremely probable that within two or three months the disease would have invaded the peritoneum and neighboring viscera, with the formation of extensive adhesions, and then complete extirpation would have been impossible. It is particularly in chronic cases of appendicitis that a patient can be easily relieved of an organ which is capable of causing serious disease and even death, and relieved in such a way that there is absolutely no harm done to the individual. On the contrary, the life of such an individual is more valuable after the appendix is removed. The operation is attended with little or no danger, and there is no resulting mutilation.

Virulence of the Diplococcus in Human Saliva, According to Age and Season.—Efisio Murgia concludes from experimental researches that the diplococcus is most virulent in persons under ten or over forty years of age. Low atmospheric pressure and low temperature, abundant rain and dampness appear to favor the pathogenic action of this organism.—*La Riforme Medica, August* 14, 1901.

Sudden Death of Children.—Martin Themich (*Vierteljahrzahrsschrift fur Gerichtliche Medicin und offentliches Sanitatswesen*) says that in severe coryza sudden death sometimes occurs by means of the so-called aspiration of the tongue, and perhaps enlargement of the uvula. In inflammation of the finest bronchi during the first few weeks of life, sudden death occurs without previous symptoms; the perforation of caseous glands into the trachea causes sudden death, and during pneumonia it is not uncommon. The presence of ascares in the trachea is most likely due to post-mortem emigration, and does not cause sudden death, and the aspiration of stomach contents can hardly be considered as a cause. In proportion to adults, sudden death, due to circulatory disturbances, is rare in children; in these cases it is most frequently due to cardiac paralysis, dependent upon the infectious diseases or nervous influences. Sudden death sometimes takes place in gastrointestinal disease, even when after emaciation and increase of weight take place; the latter gives a poor prognosis, because in these cases it is due to cardiac weakness. Enlargement of the thymus causes tracheal stenosis, but not sudden death, despite the statement of Soehla, who speaks of ryperthymisation, that is, an accumulation of toxic thymus products in the circulation. Enlargement of the thymus, however, is an important symptom of Paltauf's status lymphaticus, which is frequently a cause of sudden death. Sudden death also takes place during convulsions and laryngeal spasm. The stanoid diseases are due to disturbances of nutrition.

Ill-Health and Animal Food.—"I give up, under all states of ill-health, the use of strong animal foods, especially beef, and I also give up these in all who, though in their usual health, are of a decidedly nervous temperament, or of the rheumatic or gouty diathesis. To all, even the healthiest, I advise their use to a very limited extent, from their tendency to bring on acute rheumatism or gout, and if taken even by the healthiest too freely and too long, causing, through deposits in the internal organs, diseases which only indicate their presence after cure has become impossible. For the young, I recommend little or no animal food till they reach the term of puberty—in this following the rule laid down by the writer of the Epistle to the Hebrews, that 'strong meat belongeth to them of full age.' There are few rules that have no exceptions, and, although beef may seem my *bête noire*, I have used it even with children, and with great benefit. In some protracted cases of diarrhœa in children a year or two old, given raw or slightly warmed, and pounded very fine, it often acts splendidly. The child usually takes it at once and greedily, and will live on it for some weeks, when the desire ceases; but the child is now cured, and can take other food. Raw beef has much in common with the albumen of white of egg, and in the circumstances mentioned I would just as soon think of giving hard-boiled egg as cooked beef. Beef slightly cooked, and in moderate quantity, is sometimes very grateful to a convales-

cent from acute disease, and for a time may be indulged in with safety and even benefit."—GEORGE S. KEITH in *The Medical Times*.

Insects as Disseminators of Diseases.—C. W. Stiles (*The Sanitarian*) says that we must distinguish between two general classes of diseases—first, those which must necessarily be transmitted by insects, and, second, those in which insects are only accidental, though in many cases important, factors. Thus, malaria is normally transmitted by mosquitos and is dependent upon them; kill off mosquitos and malaria will disappear. Typhoid fever, on the other hand, *may* be transmitted by flies, yet it is not dependent upon them; kill off all flies and you will undoubtedly decrease typhoid; but since insects are only accidental and not necessary spreaders of this malady such measures will not eradicate it. He lays down two general biological rules. The first rule, to which at present a few exceptions are known, is that diseases which are accidentally spread by insects are caused by parasitic plants, particularly by bacteria; the second, to which no exceptions are as yet known, is that those diseases which are dependent upon insects or other arthropods for their dissemination and transmission are caused by parasitic animals, particularly by sporozoa and worms.

Prevention of Ophthalmia Neonatorum.—The Paris correspondent of the *Lancet* says that while certain legislative measures relative to public health were being discussed in the Senate, a Senator, who was also a medical man, proposed the introduction of a clause making it compulsory for midwives and accoucheurs to bathe a new-born child's eyes at once with a solution of permanganate of potassium, in order to prevent ophthalmia. The Minister of the Interior consequently requested the Academy of Medicine to supply him with an outline of the instructions which ought to be given to midwives in this respect. M. Pinard, to whom the question was referred, was of opinion that permanganate of potassium ought not to be ordered specially and exclusively, as it was by no means the only substance efficacious in the treatment of ophthalmia. The recommendations of M. Pinard were as follows: (1) The distribution in all *mairies* of short descriptions of the causes; (2) immediate notification of purulent ophthalmia, everywhere and in all cases, and (3) the appointment in connection with lying-in establishments (clinics and maternities) of ophthalmologists to superintend the treatment of purulent ophthalmia, and to give the requisite instructions to the pupils, medical men, and midwives.

Rheumatoid Arthritis.—G. L. Bailey (*Cincinnati Lancet-Clinic*) groups the disease into

(1) Heberden's nodosities, the mildest form of the disease, consisting of small osseous tubercles on the lower extremity of the dorsal aspect of the second phalanges of the fingers and possibly the toes. Other joints of the hands and feet may also be affected. This is generally a local condition, but may be the beginning of the general progressive form.

(2) Partial or mono-articular rheumatoid arthritis affecting one or a few joints, and producing similar changes to a more serious degree than the preceding form, as seen in morbus coxæ senilis. Foreign bodies may develop within the joint, but visceral complications are rare.

(3) Chronic progressive form. This is the gravest form of the disease, and, although exhibiting a preference for the smaller joints, may involve any or all of the larger ones, affecting the muscles, nerves, and adjacent structures, and may, according to Charcot, involve the viscera. The local changes are mainly those of a dry arthritis.

Urogenital Neurasthenia.—B. Goldberg (*Therapie der Gegenwart*) classifies this condition into three groups.

(1) Those in which serous disease of the urinary apparatus exists, such as tumor of the bladder, stricture or recent gonorrhœa. (2) Those in which the patients have the remains of a former affection, such as an old gonorrhœa, mild degree of sterility, urethral infiltration, or chronic prostatitis. (3) Pure functional neuroses without organic changes. In the first group treatment must be directed toward the underlying disease, but with attention to the neurosis. Treatment, therefore, must not be too energetic, and short. In the second group local therapy is contraindicated, and suggestive methods alone are useful. In the third group, instrumental, and short, painless therapeutic measures are indicated—galvanization, bougies, etc.

Athleticism and Longevity.—The point as to whether athletics, as carried on in colleges, is conducive to long life is a somewhat open question. Dr. James M. Whiton, a graduate of Yale in the class of 1853, tells the tale, in the *Boston Courier*, of the first Harvard-Yale rowing regatta, and presents some instructive figures bearing on the matter. He writes as follows: "It is noteworthy that, at the end of nearly forty-nine years, nearly one-half are still living—20 of 41, or 48.78 per cent. Of the 27 who rowed the race, 15 survive, or 55.55 per cent. But in the Yale class of '53, though this included, as President Woolsey pertinently remarked, 'a great many boys,' only 50 now survive of 108, or 46.29 per cent.; of the Harvard class of '53, but 40 of 90 survive, or 44.44 per cent." These facts would seem to show that the practice of athletics does not shorten life, but at the same time it must be borne in mind that in those days sport was not carried to excess. It was pursued more for the fun of the thing, and not, as nowadays, regarded as a very serious business, one almost of life or death. Training in colleges in America is at the present time abused, the result being in many cases a breakdown of the nervous and physical organization, not unfrequently ending in death.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended September 14, 1901:

A MATTER OF INTEREST IN BLOOD STRUCTURE STUDY.

By WOODBRIDGE HALL BIRCHMORE, M.D.,
BROOKLYN, N. Y.

THE drawings, on which this is commentary, were made with pencil, using an oil immersion two millimeters, by Zeiss, with compensating ocular twelve and the camera lucida, from slides prepared as blood spreads.

The Material Used.—These spreads were made from blood, still fluid, which had been effused into the great lymph space between the deep muscles of the neck of a turkey, consequent upon the cutting of the carotid artery by way of the mouth. The knife thrust had opened the way into the lymph space, and the blood had filled it and, coagulating superficially, had self-sealed the wound of entry. The head and neck were dissected not less than 120 hours after killing. The effused blood was at this time still fluid (the bird's carcass had been in the refrigerator practically the whole period) but was thickened, as by the absorption of the watery portion; the blood was about as fluid as glycerin at 25° C. There was no hint of a clot, and the blood was removed with a pipette. The spreads were stained in various ways, with the Ehrlich "neutrophile stain" the Biondi-Ehrlich-Heidenhain mixture, and with the hæmatoxylin alum, using eosin as a counterstain.

The Drawings.—As stated, these were made with the camera lucida and the pencil. Those familiar with such work will make the criticism that in the drawings certain details show more plainly than was possible in the slides. In a way this criticism is just, but it is quite impossible in giving the correct values to the intensity of the blue stain to avoid this, as the predominating yellow can hardly be indicated more strongly than has been done without results entirely misleading. I seek to prevent the misleading of any, who might be misled, by the statement of the unavoidable difficulty and the way of escape which was chosen.

The Figured Elements Shown in the Drawings.—The drawings are intended to represent certain figured elements, as follows: Nos. I. to V., inclusive, represent the large cells containing eosinophile granules; Nos. VI. to VIII., inclusive, the so-called red corpuscles, the nuclei staining blue; IX., the cells containing small granules staining blue, *i. e.* methylophile granules; X. and XI., the cells containing large methylophile granules. No. XII. represents certain methylophile cells of uncertain function; XIII. is a diagrammatic representation of a nucleated cell, from swan's blood, treated with osmic acid; XIV., the same treated with acetic acid and potassium bichromate; XV., masses of protoplasm containing granule; XVI. is a view of a few of the corpuscles of the blood under discussion, as seen with the amplification and optical combination ordinarily used by the practitioner, a B. & L. $\frac{1}{6}$-inch and a 1-inch ocular. This last was made by my friend, Mr. Davenport Hooker, at his suggestion: "they will go looking for such changes with a dry $\frac{1}{6}$ and an inch eyepiece, and because they cannot see the changes will say they never happened; best show how they look with a $\frac{1}{6}$." My thanks are due him for other and most efficient aid.

When the slides were examined, the first point which attracted attention was the unusual condition of the nuclei of the red corpuscles. No one who has given much attention to the blood of birds, especially of the domestic fowls, can feel much surprise at finding blood corpuscles of the colored variety without nuclei. It boots not to inquire if the evacuation of the nucleus takes place normally as an event in the life history of the cell, or if it be a post-mortem change, or is induced by manipulation; the fact remains the nucleus is evacuated from many cells in every spread of normal blood. It therefore would not be surprising to find red cells without their nuclei; but attention was attracted by the fact that the nuclei had not been evacuated nearly so frequently as experience suggested that they should be; *per contra*, there were by comparison very few cells which had lost them. This circumstance alone would have marked the blood as unusual. At VI. are shown two cells which interested me greatly. It will be noticed that the body of the nucleus has stained nearly the same density throughout, saving a kind of condensation (in the upper one) which I have sought to indicate by deepening the tint as the blue tint was deepened in the specimen. If the deepening of the tint indicates condensation of the karyoplasm, a condition looking toward regeneration or rejuvenescence must be under way. It will be noted in the irregular condensation, that there is, so to say, another within it—a spot in form accurately circular appears. In the adjacent cell there are a number of rather sharply defined round bodies in the nucleus. This representation does not quite please me, but I cannot do any better; the edge is unsatisfactorily defined; it is not shown too exactly, but the representation seems more sharply differentiated than the original. The edge, as seen, seemed to be of a deeper color than the rest, and yet I could not determine if this were due to a real condensation of color-accepting material, to a material-taking color more intensely, or to a phenomenon of refraction. My inability to decide such a question will have been shared by those who have worked much with the objects on the border of certain interpretation; to pronounce positively on such questions is often totally inconsistent with real work. In regard to VII., the same dissatisfaction was experienced; but here, although, perhaps, less distinctly than is indicated, the refractile border certainly exists. No. VIII. shows a number of indistinct darkened spots, less distinct than those in VI*b*, more distinct than those in VI*a*. If we assume the apparent gradation, VI*a*, VIII., VI*b*, VII., we have an orderly sequence in appearances. But have we the true sequence in development? If so, then two questions rise: (*A*) Have we before us a few links in a long chain of which both ends are prolonged beyond all guess; or a completed, or nearly completed, cycle of development of which only the

first and last steps are wanting? In passing, it should be mentioned that the vast majority of the red cells present the coagulation figure of which XIII. or XIV is the type. But why do not all? What is the reason for the divergent type? What was the condition antecedent to the change? While nothing certain can be said, I am inclined to suspect that the following is the most probable explanation. The life of the tissue elements must be but a short one, even if it extends to days. If we

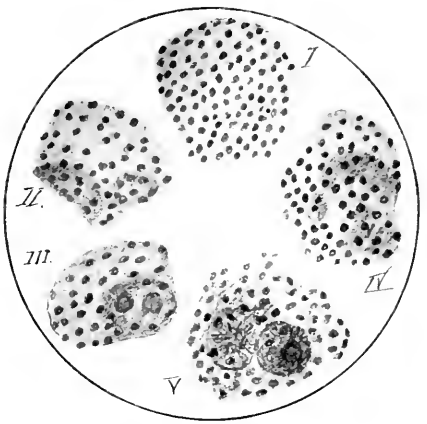

FIG 1.—Colorless Corpuscles. Stained B E H Zeiss 2 mm oc 12 · 2000

assume, and I think we may, that up to a certain point in the life of the cell, reproduction by nucleus regeneration is a fact, then these red cells which had passed the point in their life history at which this regeneration is possible would remain, under the conditions of the experiment, adult survivors of a previous age; endued with a spurious, because artificial, longevity. Protected by artificial conditions from their natural fate, they remain passive, senile survivors, unable to take any part in the growth-processes going on in the tissue about them. *Per contra*, the conditions being unusually favorable, on this hypothesis, for the cells capable of regeneration, because already adult they were not yet senile, these would set about the process of reproduction with all their stored energy. During the growth-process ensuing, the embryonic tissue produced, being for a time undeterminate, might end in the production not of red blood bodies, but of any tissue capable of production from the germinal layer to which these embryonic tissue cells might, from their origin from red blood cells, potentially belong; that is, the embryo cells would functionate not as red corpuscle nuclei, or formation cells, but as formation cells to tissue elements of the blood-cell group at large. Since the life of a blood cell is probably relatively a short one, there could not be very much difference in the point at which the various regenerated cells would take up the task, and it might be that they would not only be actually few, but relatively still less numerous because of the really enormous number of cells belonging in other categories.

Further, (*B*) did they all take up the new life motif *ab initio*, or did they enter on it at various and sundry points depending on their previous history and development? I believe the second hypothesis more likely. For a certain period of greater or less duration, the life of every cell must be indeterminate; then, so long as this period was not passed, the older cells would continue the indifferent development with a certain advantage over the younger ones. This, within limits, would explain the conditions met with; and, if accepted, would, at the end of a given period of time, bring the oldest of the regenerated cells somewhat further in the renewed development than the youngest; this would be all, and it would seem as if something analogous to this hypothesis had actually come to pass.

Nos. VI*a*, VII., VI*b*, VIII., then, represent only a few stray links in a longer chain; no one can say how long, of which the remaining links may explain many at the moment unexplained and unexplainable facts. These must be sought for, and, if possible, found, after which a new chapter in the healing process, and in those errant healing processes producing pathological growths, will, maybe, be written.

The same unsatisfying condition of half knowledge is all we can reach in reference to the eosinophile granule cells, I. to V., inclusive, as in the case of the erythrocytes we find them all in one or another of a limited series of conditions. If we assume that all the erythrocytes were between *n* and *r* hours old, so we may characterize these cells which contain granules as being representatives of a limited series of which the ultimate members are wanting at both ends. There is not one eosinophile granule cell upon the slides, some twenty in all, which I have examined, and in which every known eosinophile cell is listed, and in many instances carefully drawn and described, which does not fall between the same limits as the cells sketched here if the development of the nuclear system is taken as a guide. When the study had progressed far enough to recognize the relations in a general way, I imagined that these five figures might be said to represent very fairly all the important steps in development within the limit set by the progress of growth, hence these drawings; but more extended study showed that, while the extremes are not changed, the number of intercalated steps must be increased many fold.

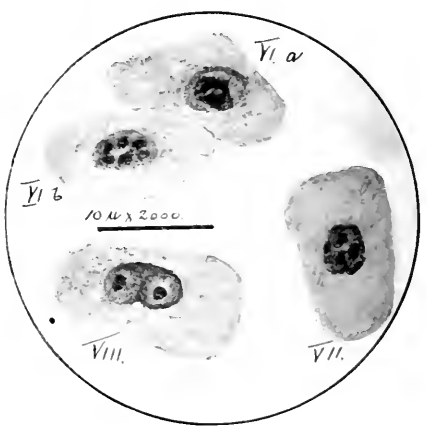

FIG 2.—So-called Red Cells. VI. Stained B. E. H.; VII., VIII. Ehrlich 3 acid. Zeiss 2 mm comp. oc. 12. × 2000.

Already about twenty stages are distinguishable, marked partly by the development of the nucleus and partly by that of the granules.

In addition to the changes in the nucleus (the methylophile portion of the cell has received this name by common consent, although nucleus in its proper sense it can hardly be) certain changes are to be observed in the eosinophile granules themselves. Their origin, supposedly determined, will in time become a burning question; for in the granule-contain-

ing cells are there not only granules of every size, but at times the granules are twins, true figures of eight. One might almost imagine that they increased in number by division after attaining a certain bulk. This, however, is probably quite out of the question, and would not be suggested as an hypothesis, even by the wildest imagination, still the hypothesis could be defended for a while. For the present, I say no more of them, as I wish to embody all my information in a more satisfactory form at a later day. There is

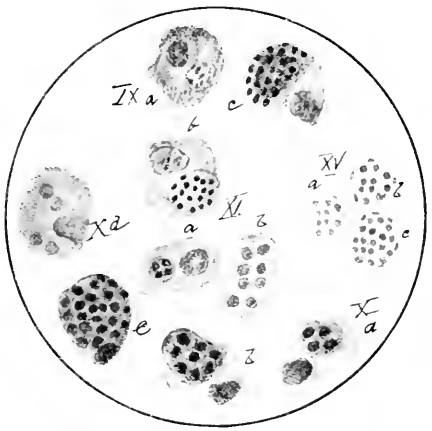

FIG. 3.—Blood Elements not Definitely Classified. XV. Ehrlich 3 acid stain; the other Grubler B. E. H. stain Zeiss 2 mm. comp. oc. 12. 2000.

one item of interest in this connection which not only invites but demands attention, namely, the free granules. Scattered about among the cells of all my slides are groups of eosinophile granules; some contain only a dozen, some twice as many, and one group on another slide contains forty-three granules. From their arrangement, one would say that these granules are contained in cytoplasm. But if so bedded, the containing mass is a cytod, not a cell, for it has no nucleus, no blue organs whatever. Whence come these groups of granules? Not from rude handling of the material; the method of mounting prohibits this, if it presents no other advantage, strain on the anatomical elements there cannot be. Leaving for a moment the question of the method of escape, I wish to draw attention to the fact that in many cases the granules in these cells seem to be outside the cell wall, or at least the cell wall is so thin over them that they seem to be rather outside the cell than in it; the appearance suggests cherries stuck in transparent jelly. The granules having this relation are not only the largest, but they are all of nearly the same size. One can but ask, does the granule-containing cell go to pieces? Are the granules extruded, carrying with them a part of the cytoplasm? If so, what is the after-history? Indeed, what is *actually known*, observed, published, verified in regard to the life-history of the blood elements, compared to the number of questions for which answers are wanting? In this case, as in so many others, we have a penn'orth of bread (observed fact) and an inordinate deal of sack (inference), as Prince Henry says of the contents of Falstaff's wallet. Three of these detached groups of granules and the containing protoplasm are shown at XV. They are taken from different slides, but in all the conditions were alike. A granule-containing corpuscle, with the granules to all appearance completely outside, or at least in the extreme superficial, surface is not far off. It has never been my good fortune to see the division, but it would not be surprising if a corpuscle with the condition shown at the lower half of II. were to extrude some of the granules, and hardly more surprising if a portion of the cytoplasm was extruded with them. This granted, a spherical mass of cytoplasm-containing granules, but no nucleus, a cytod, in fact, would most obviously result.

There remains for consideration the "methylophile bodies." These include all those which take the blue color, no matter what their origin may be, which is in effect, so far as this inquiry is concerned, purely an academic and speculative question. These methylophile cells or cytods, or elements resembling them, are those figured as IX., X., XI., XII. Of these X. and XI. may be various stages of one form, if so, the order of development would seem to be XI*a*, X*a*, X*b*, X*c*, XI*b*, while X*d* is an aborted condition. These will hereafter be discussed as the "methylophile cells with large granules," or as "large granule cells" for short. IX. represents an entirely distinct element form, which may very properly be called the "methylophile cell with small granules," or the "small granule cells." XII. represents an element which I have never before seen in the blood of any animal. In fact, so far as I can remember, it is a form entirely unknown to me. In some slides examined there are none to be found; in others there are several, still they are very few, and it would be no exaggeration to say that they are excessively rare.

Discussion of these various forms can in this paper be made but briefly, still there is room to show their suggestive character. Starting with IX. and X., we note that cells closely resembling them in shape, organization, and staining reactions, and in the size of the contained granules, have been pictured by Von Jaksch in his chapter on the pseudo-leukæmia of infants. Indeed, if my interpretation of his plate is correct, they would be indistinguishable one from the other. Von Jaksch gives no extended discussion, but I fancy that, in both cases, the cells are true

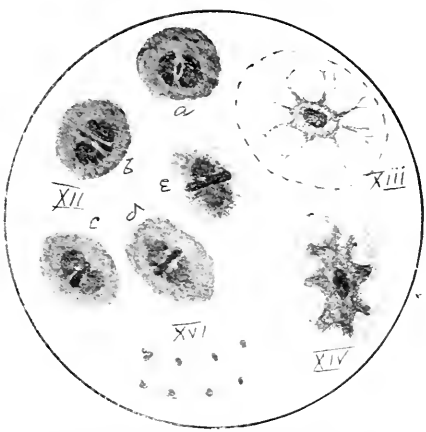

FIG. 4.—Various Blood Elements. XII. Grubler B. E. H. stain, oil im., 2 mm. comp. oc. 12; XVI. Hæmatoxylon-eosin B. & L. dry 1 inch objective with inch ocular, × 420; XIII. XIV are diagrammatic

"leucocytes," and, in all probability, "lymphocytes" as well. The position in which the blood specimen was found would justify this conclusion apart from any further consideration. It is plain that the indications of the life history shown here exhibit but a small part of the whole cycle; still enough is shown to justify much study and not a little speculation, yet no generalization, however tentative, would be even excusable.

The small granular cells are equally interesting,

and, if anything, still more difficult to identify. They do not resemble accurately any element ordinarily found in the blood of birds nor of reptiles, but they do surprisingly resemble certain cells found from time to time in embryonic structures in tadpoles and newts. Their special resemblance to cells sometimes found in the gills of embryo frogs must strike anyone who has studied such embryos; they resemble them even in the detail of the double contour of the granular nucleus. They also resemble certain other embryonic structures, *e.g.* the round corpuscles which appear in or near the surface of the gill, in that only one portion of the divided nucleus is granular. But they differ from them in the fact that the whole of the karyoplasm seems to be converted into methylophile granules. For a long time past, ever since Professor Gage read his paper on Necturus, 1882, I have been indulging the hope that some one would see the evacuation and after-development of this granular nucleus, and follow its changes from a methylophile to an eosinophile body. It is quite conceivable that the granular nucleus might be evacuated and developed into eosinophile corpuscle of the blood, which we call the "white blood corpuscle." The only difficulty in the way of accepting the notion that the nuclei of these small granular cells have some such formative function is the completeness of the change to granules. It is, however, possible that the artificial character of the surrounding has affected them, as it obviously has the "red cells." It must be remembered that this blood is in a lymph space, is mixed with another fluid of a character quite unlike blood, which is far less specialized, and it is really possible that these cells properly belong in the lymph and not in the blood. There is another point to be considered not without interest in this connection. We frequently find in the blood of mammals a blue granular cell which bears a marvelous resemblance to a small eosinophile cell, barring its staining reaction. We also certainly know that cells do change from a methylophile to an eosinophile condition with age; this being an attribute of the cytoplasm and confined to it, and not in any way affecting the relations of the karyoplasm; for example, the cells in the foot of very young, unhatched larvæ of Limulus and Crepidula, and certain cells in the "gills" of the oyster. If this faculty belongs to unspecialized cells in one organism, there is no good reason why it should be denied *a priori* to embryonic, or at least unspecialized, cells in any other. If this is tenable as a "working hypothesis," as a proposition in biological geometry, to be examined and to be proved right or wrong, and it is not suggested as anything else, it might be stated in this form: Theorem (using the method of Legendre's Euclid), "I say that the so-called white blood corpuscles, containing eosinophile granules, are formed from a karyoplasmic structure differentiated within the methylophile cells with small granules; the change from methylophile to eosinophile structure being the accompaniment of the development from an embryonic to an adult condition."

This theorem is not a matter of personal opinion or belief; it is simply a theorem, a concrete proposition which may be studied and proved or disproved by investigation in my laboratory or that of another. It is proper, however, to say that while I have chosen for promulgating it an occasion offered to me by this blood, I have for a long time had in mind the intention of publishing an article in some suitable journal with this proposition for its burden. The reason for its present publication is simply a fitting opportunity.

Turning from these cells to those shown in XII. is turning from a form analogous at least to something well known to an inquirendum quite foreign to any figured element pictured anywhere within my ken. During the months which have passed since this material came into my possession, I have studied these cells for hours and hours, and, do my best, I can form no theory which fits the appearances except the following: In a form of cell, no longer existing in the material when the mounts were made, this figured element consisted simply of a mass of cytoplasm, perhaps with a cell membrane, perhaps without one. In this mass of cytoplasm, condensation took place, forming the more shaded portion which in *a* has already divided, forming two apparent nuclei, and between them a band with less absorption power, or less thick than the masses on the two sides. At *b* these have become contoured, and contours seem to belong both to the divided nucleus *(sic)* and the intervening mass. The remaining figures show the changes within the limits of observation. The only explanation possible is that these are eggs, or some other bodies quite foreign to the blood, or that they represent forms in some way concerned in the growth of some element of the blood. If this element is an erythrocyte, then the figure XIII., which is from an osmic-acid preparation and the chromate, *i.e.* acetic-acid result diagramed at XIV., represent the ultimate condition of XII. I do not care to speculate on this subject. I draw these cells simply for the sake of recording the fact that I have seen them, and I intend to find an opportunity for further study before I hazard even a guess at the meaning of the forms shown here.

Only one point remains for discussion here: How did it chance that the blood did not coagulate, and that the changes, which seem to be development changes not quite usual, took place? *Why* these happened, it stands to reason, I cannot know; I cannot even hazard a rational guess; but may it not have been some function of the situation and the temperature? It is well known that certain structures, *e. g.* the hair, retains its power of growth under certain conditions for many hours after somatic death even in the human being, if decomposition is prevented, especially in the case of those who have died suddenly, being well nourished. This fowl was very fat, his body was saturated with food, the blood was peculiarly in condition to feed the corpuscles which might be regarded as the only living cells left in the body. Equally, if food was plentiful, air was not, but the condition of excess of food and deficient respiration is particularly that of embryonic existence. At the same time, the conditions differed; the temperature of embryonic life is very high, here it was depressed. Does this combination of ample food with deficient respiration and insufficient heat explain the pertinacious following in the steps of development impressed upon the substance of the cells, the exceeding slowness of metabolic change, the persistence of these shadows, these simulacra, of embryonic conditions? If so, one is tempted to ask, "What would have happened between the condition reached and the moment when the pseudo-embryonic tissue, its growth-impulse exhausted, or no longer protected by environment, was assailed by the agents of decomposition?" The answer to this question is easily given, "We do not know."

341 Adelphi Street, Brooklyn

Professor Rudolph Virchow, whose eightieth birthday will be celebrated by his admirers all over the world on October 13, will receive special honor in his own city. There will be an official banquet given by the city authorities at the Rathaus, and as a further token of appreciation Berlin will give 100 000 marks to the Virchow foundation.

REPORT OF A CASE OF INTRACRANIAL TUMOR; OPERATION; RECOVERY.*

By WILLIAM M LESZYNSKY, M.D.,
NEW YORK CITY.
CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL; NEUROLOGIST TO THE DEMILT DISPENSARY, ETC.,
AND
JAMES H. GLASS, M.D.,
UTICA, N. Y.
SURGEON IN CHARGE, PAXTON HOSPITAL.

On the 27th of May, 1899, Mr. E. P., fifty-six years of age, merchant, of Utica, N. Y., was kindly referred to me for examination and diagnosis by his physician, Dr. James H. Glass of Utica. The following history was obtained from the patient:

He was in good health until two years ago, when he first noticed occasional cramp in the calf muscles of the left leg after lying abed and asleep for a few hours. This local muscular spasm was painful and severe, lasting two or three minutes. It occurred once a week for four or five months. During this time, he also noticed that occasionally while walking, he would be unable for a few moments to move the left foot forward. There was also occasional "twitching" and "jerking" of the left leg, immediately followed by inability to move it. These attacks occurred from once a week to twice in one day, gradually increasing in frequency and severity, and also in the degree of transient weakness until five months ago. During the intervals the leg remained normal. Eight months ago, the left leg became heavy and "dragged," and he frequently tripped and fell. This weakness has increased rapidly. He is easily fatigued. There has been neither "jerking" nor "twitching" during the last five months. When the spasm in the leg was most severe, the left hand and forearm also jerked. He now complains of progressive loss of power in the left arm and hand, but the clonic spasm has subsided. There has never been any disturbance of speech or consciousness, and neither the face nor the right side of the body has ever been involved. No defect in memory, judgment, or attention. Neither headache, vomiting, nor vertigo. No diplopia nor other visual disturbance. No history of injury of the head, and he positively denies any known syphilitic infection. Family history is unimportant. He has always been moderate in the use of alcohol. He sleeps well. Appetite variable. Digestion good. Bowels regular.

Examination.—Pulse 84 and regular. Slight arterial tension. Heart, accentuated second aortic sound. Lungs and abdominal viscera normal. Pupils equal at 4 mm. Reactions normal. Vision, R. E., $^{20}/_{30}$; L. E., $^{20}/_{20}$. Fields for white and form slightly contracted in all meridians. R. E., hazy vitreous and neuroretinitis; L. E., receding papillitis. Hearing, taste, and smell normal. No aphasic symptoms. In percussing the skull no tenderness is complained of. Tongue and facial innervation normal. *Left upper extremity.*—Paresis affecting all extensor muscles and shoulder girdle. Grasp with dynamometer, L., 65 (R. 100+). No atrophy. No muscular rigidity. Elbow-jerk active. No objective sensory disturbance. No astereognosis. Right upper extremity normal.

There is no static ataxia. In walking, he drags the left leg. He is unable to stand on the left leg alone. The flexors are partially paralyzed, and there is also some paresis of the extensors. The foot is extended in the position of talipes equinus on account of paralysis of the tibialis anticus muscle. He is able to extend the toes. There is no muscular rigidity. The left knee-jerk and the Achilles reflex are exaggerated. No ankle clonus. Plantar reflex of normal character present, but weaker than on the right side. Abdominal reflex not obtainable (pendulous abdomen). Cremaster reflex feeble on the left side. No atrophy. No objective sensory disturbance. Right lower extremity normal.

Result of examination of urine negative.

Diagnosis.—Intracranial tumor of slow growth involving the arm and leg centers in the cortex of the right hemisphere. Character of neoplasm undetermined. On account of the increasing hemiplegia, exploratory operation was advised, and, if practicable, removal of the growth.

*Read at the annual meeting of the American Neurological Association, June 20, 1901.

OPERATIVE PROCEDURE FOR TUMOR OF THE BRAIN.

By JAMES H. GLASS, M.D.

In confirming the diagnosis of tumor of the brain, Dr. Leszynsky had advised a course of medical treatment with inunctions of mercury and increasing doses of iodide of potassium. This had been followed for nearly the prescribed time without appreciable change for the better, and an exploratory operation was then decided upon. Preliminary to this, the head was carefully shaven, sterilized, and diagramed after the method of Müller, as modified by Kocher, with the aid of the instrument devised by Dr. Schenk of Berne, the lines being drawn with a strong solution of silver nitrate, that indelible yet surgically clean landmarks might be present at the time of operation, thus avoiding possible confusion.

The method is as follows: An equatorial line is drawn, the margin of which strikes in front the crista glabella, is limited by the occipital protuberance behind, and skirts the upper attachment of the auricle on either side; a meridional or sagittal line is traced from the crista glabella in front to the occipital protuberance behind. Over a point midway on this line is arranged a graduated disc, and anterior and posterior oblique lines are traced at an angle of 60° intersecting the equatorial line. The tracing of the fifth line is more difficult. The sagittal meridian is divided into three equal parts, marked anterior and posterior third point; the posterior half of the sagittal meridian is again divided into two equal parts, anterior and posterior fourth point; midway between the posterior third point and the posterior fourth point an oblique line is traced around the skull intersecting the equatorial line at a point 1 cm. posterior to the intersection of the anterior oblique line. This method, though somewhat complicated in its description, is very simple of demonstration with the instrument of Dr. Schenk. According to the classification of Horsly, the anterior oblique line of the diagram would indicate the motor cortex involved in the above case, *i.e.* the arm, hand, leg, etc. With the aid of the De Vilbiss surgical engine, which we have found most efficient in all varieties of bone-surgery work, a large omega-shaped osteoplastic flap was turned back, care being taken to preserve the relations (therefore the nutrition) of the scalp and cranium and the dura exposed. The feature of this, as indeed each successive step in the operation, was the profuse hemorrhage encountered, it being necessary to overcast all soft tissues and plug with bits of bone the nutrient canals of the cranium. The vessels of the exposed dura were engorged with blood, and were ligated before this membrane was incised, which done, revealed almost centrally located in its relation to the opening, the convex surface of the growth pushing out above the surface of the brain. The tumor was enucleated

up to the longitudinal sinus, to which it was attached through the falx cerebri, and from this membrane it was carefully dissected off. In shape, the tumor was nearly spherical and about 20 mm. (¾ in.) in diameter. The oozing continuing troublesome, it was thought best to pack the wound for forty-eight hours with strips of gauze tape, the ends of which were brought out through drill holes in the angles of the wound, after replacement of the osteoplastic flap, which was secured with silver wire. On account of the great vascularity of the field invaded, this case would have been operated most advantageously after the two-stage method of Horsly. The patient made a good recovery from the effects of the operation.

We are indebted to Dr. C. W. Kinney, pathologist to the Manhattan Eye and Ear Hospital, who made the microscopical examination of the growth, finding it to be an endothelioma.

We saw the patient together two months after the operation. At that time, there was almost complete paralysis affecting the left upper extremity. He could only flex the fingers, and feebly flex and pronate the forearm. In the lower extremity the posterior thigh muscles were paralyzed. The knee-jerk was highly exaggerated and accompanied by ankle clonus. There was no objective sensory disturbance; no astereognosis; but muscular rigidity was present on the hemiplegic side.

A recent letter of inquiry addressed to Dr. Glass, who still has the patient under observation, elicited the following reply:

"I saw Mr. P. yesterday, and secured answers to the questions which you suggested. There seems to be no impairment of sensation. The condition of the left arm and leg changes little. The condition of muscular rigidity is less marked, yet quite apparent. Response to motor impulses, while still delayed, is, I think, better, an opinion concurred in by his daughter, a trained nurse, and his office mates, although the patient seems loth to admit this and some other signs of improvement. Several times each month, averaging perhaps four, and usually during bed-time, he has some muscular twitching or convulsive movement of the hand and arm, sometimes extending to the leg and foot. As a result of these attacks, there is more or less muscular fatigue. He moves about briskly, walking as rapidly in a straight line as the average individual, greater uncertainty being apparent in the more complex movements, such as turning quickly, etc. He has no general convulsive seizures, headache, or vomiting, and his general health is excellent. He is employed daily as an accountant."

A few weeks ago, the eyes were examined by Dr. T. H. Farrell of Utica, with the following result:

"R. V., 20 40; 20/15 w—.75 ax. 90°; L. V. 20/15.

"Ophthalmoscopic examination: Right, physiological cup obliterated by former neuritis. Level of disc same as retina. Slight haziness of disc and surrounding retina. Macular region normal. Left, normal. Opaque nerve fibers up and in from disc."

This case is recorded as an additional instance in which an intracranial tumor has been accurately localized and successfully removed. The operation was performed two years ago, and the patient is now following his daily occupation as an accountant, the present condition of partial hemiplegia being the result of the destruction of brain tissue previous to the removal of the growth. A noteworthy feature in the present case was the entire absence of headache or vomiting during the course of the disease.

Had the diagnosis been made about two years earlier, when the symptoms clearly indicated involvement of the leg center in the cortex, and an early operation undertaken, the patient would have been saved from the incapacity induced by a permanent hemiplegia.

THE PROPHYLAXIS OF TUBERCULOSIS.

By JOSEPH KUCHER, M.D.,
NEW YORK.

Before advising prophylactic measures against any infectious disease, it ought to be considered whether the proposed measures are practicable and whether the obtainable results are worth the efforts and costs by which they are obtained. Sanitary laws and regulations which are enacted in disregard of these precautions meet soon with so much silent or open opposition, that they remain a dead letter. And laws that are not and cannot be enforced are always harmful. For this reason the laws proposed by several boards of health against the spreading of consumption are of very doubtful utility. A still greater objection to them is that they lay too much stress on things of minor importance to the neglect of things of paramount importance. The measures that have been enacted or proposed are all based upon the supposition that the greatest danger in regard to consumption arises from infection. This is a dangerous belief, as it leaves the public to the fallacious conclusion that it is more important to keep away from the danger of infection than to observe the most necessary sanitary laws. And then, this belief in the dangers of infection is not founded upon undisputed facts. Many physicians with large experience in the treatment of consumption either deny the danger of infection altogether or concede to it only a slight importance

Dr. Brehmer ("Aetiologie der chronischen Schwindsucht") says: "Since 1854 there have been in Gerbersdorf more than 10,000 consumptives. What quantities of sputa have not been ejected on either the paths or public highways! What quantities of such sputa, such infectious matter, have not been carried into the air which has been breathed by the inhabitants of Gerbersdorf! and the percentage of consumptives among them during the last twenty-six years has decreased from 0.41 to 0.18 pro anas."

Dr. Pollock (*Medical Examiner*, February, 1899) says: "As regards infection, Dr. Williams and I have investigated it at the Brompton Hospital, from the very beginning until now, that is, nearly fifty years, and there have not been among the nurses, among those who scrub the floors, among the physicians, house physicians, dispensers, and others, more than four cases in fifty years. I have found that, out of about 4,000 cases which I have attended in hospital practice and investigated, at least thirty per cent. have had the hereditary element."

The same experience has been made in other hospitals for consumptives. In the State of Massachusets in former years fifteen women to ten men have died from consumption. So in the last ten years the mortality from consumption decreased for men and women, but considerably more for women as only nine women died to ten men. This improvement was brought about by the improvement in the food and in the manner of living, and not by any preventive measures against infection.

British barracks were formerly constructed with no regard to ventilation, and consumption was the cause of a very large proportion of deaths; since the buildings have been improved, by giving a large space and air supply, the mortality from consumption has diminished more than one-third.

In the zoological garden of Paris consumption affected nearly all the monkeys, until care was

taken to introduce fresh air, when consumption almost wholly disappeared.

There are certain occupations in which the majority of workingmen sooner or later die from consumption. M. Napias, the well known sanitarian states that eighty per cent. among the cutters of silex, seventy per cent. among needle-sharpeners, sixty per cent. among file cutters, forty-five per cent. among lithographers, forty per cent. among grindstone cutters, seven per cent. among cement workers, five per cent. among tin-foil workers, die of consumption. According to Napias, the harder the dust is the more apt it is to lead to a phthisical condition, it adheres to the mucous lining of the bronchial tubes and deranges the circulation and prepares a favorable soil for the tubercle bacillus.

It is well known what an important part heredity plays in consumption. Although the disease is, as a rule, not inherited, the predisposition to it is. Statistics of life insurance companies show that, notwithstanding the most careful selection of applicants, there is always a larger proportion of deaths from consumption among those who have a hereditary taint, and the stronger the taint the greater the mortality. And the mortality is by far the greatest among those with a hereditary taint, who neglect their physical welfare either from ignorance, carelessness, or necessity. In all large cities the percentage of consumptives increases with the density of population. If there were half as much danger from infection as some physicians want us to believe, it were most injudicious to send persons suspected of beginning consumption to places full of consumptives. It is true that some people of Southern California have begun to protest against the coming there of consumptives; not that they had any proofs of the danger of infection, but they became frightened by the general talk about the charges of infection and the preventive measures of some boards of health.

More than one hundred years ago the most stringent measures against the spreading of consumption by infection were enforced in Naples for several years. The result was a great hardship on the population without the least decrease of mortality from consumption. There is also this striking difference between consumption and other infectious diseases, that of the latter not even an experienced physician can predict which one of several persons who have been exposed to infection will be attacked, while in regard to consumption even a layman can beforehand, in many cases, tell which one is more or less sure to suffer from it. There is in most cases a pretuberculous stage, understood by the most superficial observer. Probably no case of consumption occurs which cannot be traced to irregular living, over-application to business, study, or pleasure, especially with much confinement in impure air—anything that interferes with the physical or moral well-being, and consequently lowers the vitality. Indigestion or very poor appetite in young persons is one of the earliest symptoms, and their persistence always calls for physical examination of the lungs.

It has properly been said that consumption originates in the stomach as malnutrition. These pretuberculous stages become more serious if tuberculosis has been already present in the family, or if the person is constitutionally weak or engaged in a business predisposing to consumption.

Anyone who has given some attention to the causes of consumption must soon come to the conclusion that the danger of consumption from infection is of very subordinate importance in comparison with the many other causes. It is, therefore, surprising that not only laymen but many physicians are so ready to accept, in a given case, infection as the cause of consumption without inquiring whether there are not other more plausible reasons for it. From the earliest time to the present the idea has always existed, and it has occasionally been the accepted doctrine, that consumption is infectious, but it was always understood that undoubtedly a susceptibility to it plays the most prominent part; while nowadays infection is everything. Under these circumstances the present edicts of the boards of health do more harm than good. They confirm the public and many physicians in their preconceived ideas that it is more important to avoid the dangers of infection than to observe the most necessary hygienic precautions. If the boards of health, instead of wasting their efforts upon impracticable measures of doubtful value, would concentrate their attention upon regulations of undisputable merit which at the same time are practicable, a great deal of good could be accomplished. Such a change for the better can be expected when the boards of health and the public have become convinced (1) That the tubercle bacillus is ubiquitous and that we cannot escape it anywhere. (2) That the bacillus is harmless until it finds a congenial soil. The same is true also of some other bacteria. It was shown at von Leider's clinic in Berlin, some time ago, that ordinary bacteria in the blood circulation of animals affect the heart valves only when these are already injured. (3) That the human body offers a congenial soil when its vitality is undermined by one or the other of the many causes that are deleterious to health. (4) That there is no better and surer and easier preventive against consumption than to keep the body proof against the tubercle bacillus. This can be done by avoiding the causes that make the human body susceptible to it. Foremost of these and the one most disregarded is working, living and sleeping in a confined and contaminated air. Out of all of the United States, only fourteen have laws relating to inspection of factories and workshops. In this city there are many offices and workshops deficient in the most necessary sanitary requirements, but they are ideal places in comparison with the accommodations that serve most of the poor people as sleeping rooms. Even among the better situated people the best part of the house or apartment is kept for show and the worst part for sleeping room. But most surprising is that many of the very rich build houses in which every luxury is provided for, except the most important, to wit, sunlight and good air. The next noteworthy causes that undermine the vitality are certain occupations, as before mentioned, or prolonged working to excess, worry, dissipation, and irrational feeding. Any of these causes shows its effects, of course, much sooner in a person who is constitutionally weak or in whose family there is a hereditary taint of consumption.

THE HOME MANAGEMENT OF EPILEPSY.*

By ROBERT H PORTER, M.D.,
CHICAGO.

This paper was written on the theory that the primary origin of idiopathic epilepsy is due to degeneration of the cells of the central nervous system. When these cells with impaired or perverted nutrition are stimulated into action, they produce incoordinate or perverted functional activity. The demand of the impaired cells for more and better nourishment causes an increased blood supply, in harmony with the pathological law that impaired nutrition excites local congestion. Owing to the exhaustion of the cells, they are very sensitive and easily excited by the slight congestion into perverted action, and herein lies the essential features of idiopathic epilepsy. It is a well-known fact that the post-mortem examination of the brain of the chronic epileptic shows great dilatation of the blood vessels in certain regions. This dilatation of the blood vessels is due to severe chronic congestion of the brain; in fact, the epileptic has too much blood in the brain all the time. And this corresponds with the opinion expressed by competent observers for centuries, that congestion of the brain is the cause of epilepsy.

In the treatment of the disease, as congestion of the brain is such an important factor in the production of the attacks, it is of the greatest importance to reduce the brain circulation at once, since by preventing a recurrence of the acute congestion the convulsions can be permanently arrested, and by the use of suitable soothing tonics the nutrition of the brain can be improved and the patient cured.

In the management of the patient, appropriate mental therapeutics, with a suitable psychic environment, are as important agencies in promoting the recovery of the patient as the chemical or material measures used.

Owing to the disease of the brain which is associated with epilepsy, there is a morbid psychic as well as somatic condition that must be carefully investigated, for often the psychical seizures are more important and complicated than the convulsions.

Often a word carelessly spoken or the sight of some familiar object may be sufficient to start a train of morbid thoughts, and these becoming aggravated, sometimes produce a recurrence of the epileptic seizures.

Frequently these patients are greatly benefited by being removed from their old environments. A well-organized colony, such as the Craig Colony in New York, or the one at Gallipolis, Ohio, or similar homes in other States, affords the very best place for such cases. Owing to the great improvement in the care and attention which they receive, many patients can be cured in a colony who could not be anywhere else.

Only a small number can be taken care of in colonies at the present time compared with those who must be provided for elsewhere, so that any suggestions that will serve to improve the home conditions will greatly benefit this much-afflicted class.

The home management of the epileptic is second only to that of the medical, and it is of the greatest importance that there should be the most perfect harmony, sympathy, and co-operation between the two for a given and well-understood purpose, namely, the cure of the patient. This one great object must always be kept well in view, and everything else must be made subject to it. The best results for the patient can be secured only when each and every member of the family earnestly and actively co-operates, in harmony with the medical management, to secure the greatest possible benefit for the afflicted one. Now, on the part of the patient, owing to the disease with which he is afflicted, there is confusion, disorder, deterioration, and degeneration of the brain itself, and therefore we may expect him often to be irritable or perverse and unstable in all things. If the environment is unfavorable, with more or less friction in the home between one or more of the family and the patient, not the fault of either, but the great misfortune of all, then the demon within, conspiring with the enemy without, may serve to counteract the very best medical measures that can be used.

In the treatment of epilepsy one of the greatest dangers to be feared is that from an unfavorable environment. Every one, even among those who are well, has often felt the disagreeable effects that always follow an unjust and harsh criticism, although the words were not spoken either in anger or viciousness; then how much greater and more disastrous must the reaction be in the sensitive epileptic! One illustration of the detrimental effects of a pernicious environment will be sufficient.

A refined, highly organized, sensitive young lady, an epileptic, had been for more than a year free from the attacks, with a marked improvement in her general health and every indication of permanent recovery, when one day she was harshly and unjustly found fault with. Within a short time afterwards she was seized with a convulsion, and as both her psychic and material surroundings were very unfavorable, her condition gradually developed into one of hopeless epileptic insanity. If she had received a blow on the head of sufficient force to have knocked her down and rendered her unconscious, the effect could not have been more disastrous.

Neglect on the part of the one who is charged with the care and welfare of an epileptic may prove equally detrimental. The patient, as a rule, is not competent to take care of himself, and certainly ought not to be trusted to prepare and take the necessary medicines and follow out the instructions.

He is often forgetful, irregular and uncertain about everything, therefore it is of the greatest importance for him to have systematic training, both mental and physical, so as to once more develop order, regularity, and system, instead of the disorder and irregularity which have for so long a time been the most prominent characteristics of his life.

Owing to the individual peculiarities of each patient, the great difference in the environment, and the complex problem presented by the disease itself, no fixed rules or regulations can be given for the home management. This, like the remedial measures, must be modified from time to time according to the varying conditions, and the ever-changing moods of the patient. The first great principle that must never be lost sight of, is to do at the time and under the circumstances whatever will best promote the benefit, welfare, and recovery of the patient, and which, when intelligently applied, even under the greatest difficulties and the most trying conditions, will always produce the best possible results.

Now, to apply these principles carefully to the daily life of an epileptic may often require great patience, forbearance, and self-denial; and yet it may mean all the difference between success and

*Read at the First Annual Meeting of the National Association for the Study of Epilepsy and the Care and Treatment of Epileptics, held in Washington, D. C., May 14 and 15, 1901.

failure in the treatment of the patient. The "one touch of nature that makes all the world akin" is shown when one sees a fellow-man in distress and ministers to his wants. How much more, then, is this called for when the person in distress is of one's own household? And he must be ministered to not grudgingly or irregularly, but with a free goodwill all the time.

A few of these patients, especially among children, may show some minor defects in manners and deportment or be exceedingly mischievous; it is best in such cases, as far as possible, to ignore many of their shortcomings. At least, it is exceedingly bad for the patient to have some one always reproving or finding fault with him. This may soon develop into a form of persecution or torture, and, under a feeling of injustice, the patient may develop an irritability, perverseness, or even viciousness with destructiveness.

Very much better is it to develop and encourage by all means possible the good; to notice and praise the favorable, and at the same time ignore and discourage the unfavorable—to restrain the morbid. In some instances the bad behavior may be due to a lack of mental development on the one hand, or, on the other, to emotional perversions. In either case, when carefully studied, the defects will be easily recognized as a part of the morbid history of the patient, and the same should be treated accordingly. When the underlying disease is removed, these deficiencies will surely and steadily disappear.

In these cases especially the mental environment has a very great influence over the progress of the patient, and this will serve to explain, to some extent, at least, why some patients improve so much more rapidly and better than others, under otherwise similar conditions. Therefore it is of the greatest importance that each and every member of the family earnestly, persistently, and all the time co-operate to make and maintain all the conditions, both mental and physical, most favorable for the recovery of the patient. It is only by such measures as these that the very best results possible are to be secured by the home management. When these principles are properly applied, aided by love, patience, forbearance, and self-denial, in connection with the necessary and proper medical measures, beneficial effects, well-nigh marvelous, may be secured.

One example of what may be accomplished by the aid of a favorable environment may be most appropriately given just here.

On October 12, 1900, Mrs. H. brought her demented epileptic son, aged sixteen years, to the writer to see if anything could be done to improve his deplorable condition. She gave the following condensed history of the case: He was a strong, active and ambitious boy, well advanced in his studies at school, but when eleven years old he began to have slight spasms at irregular intervals. These had gradually increased both in severity and frequency, in spite of everything that could be done for him. The parents thought they had exhausted every resource to arrest the progress of the disease, and that without any avail or permanent benefit. For the preceding year or more the lad had had an average of from fifty to sixty hard convulsions a month; sometimes the attacks would occur daily, varying from two to eight, and continue in this manner for a while, then they would change, and there would be a series of from twenty-five to thirty spasms in rapid succession, and after this probably a free interval of one or two weeks.

Notwithstanding the frequency and severity of the seizures, his appetite was good or ravenous, so that he was well-grown for one of his age, but his mental condition was such that he had to be confined at home. He could not comprehend or carry on a conversation, and if he got out alone, he wandered off and could not find his way back. The mother was devoted to her afflicted son, and had already given up everything else that she might take care of him both night and day as no one else could. She was ready, willing, and able to do any and every thing possible to promote his recovery. Under these most favorable conditions, aided by the proper medical measures, I was able to arrest the attacks at once, and the boy went two months and a half without a symptom of the old trouble; then, owing to an error in the medical management, there were several slight seizures, but these were soon controlled, and there has been no recurrence of the symptoms since. The great and rapid improvement in his mental state and the entire freedom from all of the epileptic symptoms or seizures promise a permanent recovery in due time.

In general, there are few or no rigid restrictions in regard to the diet; the patient should be careful, prudent, and temperate in all things, avoiding whatever disagrees with him, and eat light suppers. As a rule, a ravenous appetite proves beneficial, as good nutrition is one of the most important factors in the long, tedious fight against the disease. When the patient is frail, delicate, and sensitive, with the digestion and assimilation poor, appetite capricious and variable, the epileptic problem is rendered much more difficult and complicated.

Stimulants, such as beer, wine, and spirits of all kinds, and tobacco in all forms are to be avoided. In all of these things, the patient's only safety depends on total abstinence. The influence of inebriety in the production of epilepsy is sufficiently well known, and some of the worst cases of epilepsy and insanity that it has ever been the misfortune of the writer to see were produced by the excessive use of tobacco; and what may ordinarily be termed the moderate use of either whiskey or tobacco may serve to counteract the best remedial measures that can be used in these cases.

Last, but not least in the study of this phase of the subject, comes the proper training and control of the emotions, such as excitement, worry, anger, ego-mania, self-absorption, the various forms of emotional perversions, etc.

These may sometimes serve to tax to the very utmost the resources of the most skilful management, yet patience, forbearance, and perseverance in the good work will surely prevail in the end. Then as the underlying morbid conditions are removed the patient gradually but surely returns to the normal. Great and permanent benefit may often be secured by proper mental diversion.

Solomon has well said, "For as a man thinketh in his heart, so is he." This great truth is as applicable to the psychic and somatic conditions of a man as it is to his moral state. Owing to the long continuance of his disease, the thoughts of the epileptic have become morbid and perverted, and one of the first considerations is to instruct and train him into right thinking. A man's thoughts can be controlled as well as his actions. The importance of securing the active co-operation of the patient in combating his disease has heretofore been underestimated. He must be instructed in the fact that all emotional disturbances serve to make his disease worse, and that much depends on the amount of self-control and self-denial that he is willing and able to practice. Then great benefit may be secured by his own mental

effort at resisting all nervous manifestations, and he must carefully avoid everything that is likely to excite again any of the old symptoms.

A thought is one of the most potent factors in the world, and it is to-day more powerful than ever before. Admiral Dewey's thoughts in a few hours not only changed the map of the world, but also revolutionized the American people and changed the policy of the government. The thoughts of Dr. Ephraim McDowell, in a little town in Kentucky, opened up the great field of pelvic surgery. Lister's thoughts revolutionized the practice of surgery to such an extent that he is to-day recognized as the father of modern aseptic surgery. Many other suitable examples of the power and influence of great thoughts over the progress of the world will readily suggest themselves.

How were these results secured? By accident, or in a short time? Not at all. They were obtained after many years of careful investigation and study. If a man's thoughts can so modify the progress of the world, when properly directed, they ought also to aid in changing his own organization from a morbid to a normal condition, especially when working in harmony with and aided by the laws of nature.

The patient must not only be told of the importance of right thinking, but he must be instructed in the best means of controlling and repressing his morbid thoughts, and at the same time how to stimulate helpful thoughts. First of all, he must be prohibited from talking about his disease to any one but his physician, and next to this, he must stop thinking about it. While his family and friends are to encourage all the favorable indications, and aid him by pleasant and helpful suggestions at the same time, they must avoid talking in his presence about his disease, and how bad he has been, and refrain from expressing doubts of his recovery, for this will have the effect of exciting in his mind a fear of a return of the old attacks, and nothing will do him so much harm as fear-thoughts.

Since writing the above, a patient informed me that he accidentally heard one of his family talking to some one else about him, in which the opinion was expressed that my patient would never recover. He was very much depressed by this, and before the depression passed off he had one or two slight threatenings; yet during the preceding six months there had been no return whatever of any of the old epileptic seizures.

Fear-thoughts, anxiety, and worry do more to prolong and aggravate chronic diseases than all other causes combined. Now, it is of the greatest importance to recognize the difference between "fear-thought" and "forethought." Fear-thoughts are the primary cause of all worry and prove very detrimental, while forethoughts, combined with courage, are very beneficial and promote recovery. As forethought, courage, and perseverance so often prove successful in the battle of life, when properly aided by the necessary medical measures, they will be even more successful in the great battle against disease. For in the latter case, they are assisted by the laws of nature in a persistent effort to eliminate the disease and promote a recovery of the patient.

In the presence of the invalid it is certainly best not to talk about his illness, and the discussion of diseases in general ought not to be the subject of conversation. While both the physician and patient may often recognize the injury produced by an unfavorable environment, yet neither of them may be able to change the conditions. An instance in point is when there is a wealthy but cranky parent, who has strong prejudices that run counter to the best interest of the patient, and on the other hand ignorance and poverty may erect an equally insurmountable barrier.

While it is of the greatest importance to the patient to think right himself, yet it is also essential for his family and those with whom he is most often associated to aid him by an intelligent and active combination of their psychic powers to promote his recovery. Both when he is present, and also when absent, each and every one should think and talk about his improvement and recovery, say earnestly and firmly that he must get well, and do all in their power to promote this end, and the result may be wellnigh marvelous. Every one knows that a combination of the psychic power of numbers often proves irresistible, and that this great influence may frequently be felt and recognized without even a single word being spoken. Therefore, we should make and maintain all the time, and under all circumstances, both the psychic and all the material conditions as favorable as possible for the recovery of the patient.

THE VENDOME

ON THE ORIGIN OF RETROVERSIOFLEXIO UTERI AND ITS PATHOLOGICAL DIGNITY.

BY SAMUEL W BANDLER, M.D.,
NEW YORK.
ADJUNCT GYNECOLOGIST TO THE BETH ISRAEL HOSPITAL.

WHEN we consider the numerous operative methods used in correcting retrodeviations of the uterus, and the general adoption of the Alquié-Adams operation for the correction especially of mobile retrodeviations, it would seem that retroflexioversio uteri was of itself a condition demanding operative treatment.

The annoyances so frequently found associated with these displacements, such as dysmenorrhœa, sterility, metritis, endometritis, oophoritis, bladder, rectal, and nervous symptoms, have been viewed from two entirely different standpoints. The belief, on the one hand, is that complications alone are the cause of the symptoms, and that the latter are not the result of the version or flexion. Proof is furnished by the fact that before puberty and after menopause deviations are found without annoying symptoms, by the further fact that the same symptoms are present with the above mentioned conditions without uterine deviations, and by the important fact that treatment of the "complications" brings about a cure. The opposing view is supported by the statement that treatment of the deviations relieves the annoyances, that close examination shows the same symptoms to have existed before puberty and to continue after the menopause. The congestion of menstruation is considered, in the latter view, as being naturally an important element in increasing the annoyances during functional life.

Theilhaber expresses the opinion that most retroflexions of themselves cause no annoyance, that the symptoms are not the result of the retrodeviations, but are caused by other conditions standing in no direct relation to the retroflexioversio. He finds that after reposition the subjective symptoms often disappear in a few days, and yet examination shows the uterus to be retroflexed in spite of the pessary. In a large percentage of cases the patients feel no improvement, as regards their nervous systems and the local disturbances, yet frequently examination shows the replaced uterus to be in perfect anteflexion. He finds no improvement as regards fluor, in spite of reposition of the uterus, and the bleedings are diminished decidedly in very few cases. He does not believe that retroversion or retroflexion can cause a congestion in the uterine circulation. Further, the symptoms in many cases of decided retroflexion are almost nil, while in others the mobile

uterus, but little displaced, shows the so-called "typical symptoms" of retroflexion.

He does not doubt that the orthopedic treatment of retroflexion will be done away with, just as the intrauterine pessary treatment of anteflexed uteri has gone out of use.

In discussing a question of this importance, it is absolutely necessary to consider the supports of the uterus, and to remember that it is imbedded in, and surrounded by, a large amount of connective tissue. Originally, no pelvic fascia exists, since every muscle fascia is simply connective tissue, which has been developed by tension and exercise. The pelvis in the fœtus is filled with a non-differentiated connective tissue, forming the common basis for the pelvic contents, uniting and dividing the different organs, and permitting mutual movement, as well as uniting the pelvic contents to their surroundings. The peritoneum covers all the organs, and lines the depressions, covering especially the uterus, the tubes, and the vessels which run to the uterus. The ligaments are simply peritoneally covered connective tissue bands, surrounding the important blood vessels, and in them muscle fibers subsequently develop. The only ligament which is not formed passively is the ligamentum teres; it is preformed, while the others depend for their position upon the development of the uterus. While it is true that a lack of elasticity on the part of the uterine ligaments is a frequent cause of inhibition of uterine mobility, no one of them is an active factor in preserving the normal anteflexed position of the uterus. An important function of the parametria with their numerous muscle fibers is to preserve the cervix in an elevated position, and they are intended to give the uterus free play. Winter says, "The uterus may be pulled up to the symphysis, pushed into the sacrum, up to the lateral pelvic wall, or half way up to the umbilicus; the portio may be pulled down to the vulva, and all this without pain." When the uterus is pushed up or pulled down it returns to its normal place because of the elasticity of its surroundings. It belongs, therefore, to the most movable parts of the body, which fact speaks against an active influence on the part of the peritoneum or any one ligament in determining its position.

In the adult woman, the uterus lies between the planes of the pelvic inlet and outlet. In the standing woman, with the bladder empty, the uterus is in a horizontal position. The cervix is nearer the posterior than the anterior pelvic wall, and lies in a plane passing through both spinæ ischiadicæ. A perpendicular from the external os passes through the posterior portion of the perineum; from the internal os a perpendicular would pass through the middle of the perineum, while one from the anterior end of the corpus, which lies on a level with the fourth sacral vertebra, passes through the middle of the septum urethrovaginale (Waldeyer). It may be seen that, in this position, the cervix is further back, and but little lower than the fundus. The cervix enters into the upper end of the vagina at an angle with the latter, and the fixation of the vagina by the levator ani and the surrounding connective tissue, and the support furnished by the parametria, make the situation of the cervix a relatively fixed point. So long as the cervix is retained in this position and at this level, so long as the uterus, its "ligaments," and the levator ani preserve their natural elasticity, so long will the forces of pressure and tension within the abdominal cavity preserve the uterus in its normal anteflexed position.

Under retroflexion we must distinguish two forms, the congenital and acquired. Suffice it to say, that in acquired retroflexion the position of the uterus is due to such weakening of the parametria, especially the ligamenta-lata, and to such an injury to the levator ani that the resulting descent of the uterus and prolapse of the vaginal walls (independent affections) are pathological conditions which constitute not only a retrodeviation, but also an hysteroptosis. This latter condition is the important factor in the causation of numerous symptoms. It is by no means necessary that an hysteroptosis should be complicated by a retrodeviation, but acquired retroflexions and retroversions are the result of hysteroptosis. Naturally, this discussion concerns mobile conditions, for a retroversioflexio fixata involves a peritonitic affection.

It is interesting, therefore, to consider the etiology of congenital retrodeviations, and to note the frequency of their occurrence. No further proof is then necessary to establish the fact that retroversioflexio *per se* is not a pathological condition.

In the embryo, the Wolffian ducts take a course which follows the curve of the fœtal body, and the ducts of Müller make their way following closely the curved line of the Wolffian ducts. The sexual strand, which includes the ducts of Wolff and the ducts of Müller, at an early stage shows an angle which represents the situation of the future external os of the cervix. In the future development of the embryo the proximal end of the sexual strand, the subsequent uterus, takes on a position of anteversion. This position is aided by the descent of the ovaries and the remains of the Wolffian body, and by the pressure of the intestines gradually filling with meconium. This pressure can be appreciated from the fact that on the ovaries and tubes impressions of the intestines may be recognized. This anterior curve of the uterus becomes gradually more pronounced, so that in some cases the corpus uteri lies horizontal. This second resulting angle represents the position of the future internal os. In embryos in the second half of pregnancy the uterus is usually anteverted, with a somewhat anteflexed corpus. In the newly born the uterus rarely lies in the median line, but shows, as a rule, a deviation to one side or the other. It lies partly within the large pelvis, and the fundus projects above the inlet. It is therefore seen that anterior inclination of the uterus, with more or less anteflexion of the corpus, is the original position depending on certain processes of embryonal development (Nagel).

In the newly born fœtus, the intestinal tract and the urachus are thin tubes, while the genital tract fills out the remainder of the long, narrow pelvis, and the relatively large uterus lies mainly above the symphysis. The bladder is not yet unfolded, is long, and its fundus remains for a long time above the symphysis. With the gradual development of the bladder from its pyramidal to a round form, the pelvis also undergoes changes whereby it is no longer a straight continuation of the abdominal cavity, and its axis forms with the axis of the latter an angle which gradually becomes one of 90°. The pelvis becomes wider, and the urethra is no longer a straight continuation of the bladder, but forms with the long axis of the latter a curve which is concave anteriorly. The uterus, which in the fœtal period filled out almost the entire straight, narrow pelvis, is now only a small dependence on the posterior wall of the bladder, and, lying parallel to the main axis of the pelvis, the uterus takes on with the changed inclination of the latter a still more anteverted position. The anterior inclination of the pelvis becomes later still more pronounced, and is necessary for several reasons. One reason is that the bladder, when filled with fluid contents, would otherwise be carried as a burden by the elastic pelvic floor alone, and a full emptying

of its contents would be impossible, for the lowest point of the pelvic floor in an upright position would lie lower than the external opening of the urethra. If, then, the pelvis did not take on a forward inclination, a condition like that in cystocele would result, for the bladder of the female lies deeper than that of the male (v. Arx).

The ovary descends from its point of origin at the sides of the upper lumbar vertebræ, and lies in the newly born on the psoas and the vasa iliaca externa. Its final position in the fossa ovarica is gained during childhood. The ovary is connected with the tube and the ligamentum ovarii proprium, but does not make the complete descent which the testicle does, although conditions are favorable, as is proven by those cases where the ovary or tube is found in the canal of Nuck. In the ligamentum genitoinguinale, later the ligamentum teres, is a muscle homologous to the cremaster. The ligamentum suspensorium ovarii is the former plica phrenicomesonephrica.

Although embryonal processes bring the uterus into the position known as anteversioflexio, errors of development may be the cause of malposition. The formation of a short vagina, with an embryonally long cervix and small fundus, displaces the cervix so that it lies close to the anterior pelvic wall, and the action of abdominal pressure may then change this retroversion into a retroflexion. In the descent of the ovaries the presence of a short ligamentum ovaricopelvicum prevents the normal anteflexion of the uterus, so that, even if other factors produce no further change, a retroversion exists. Küstner finds a poorly developed corpus and a straight stretched retroverted uterus to be often present in a poorly developed fœtus, while in a well-developed fœtus a normal, flexible anteflexed corpus is the general rule. Further, a fixation of the portio near the anterior pelvic wall, as a result of a poorly developed or short anterior vaginal wall, is productive of a malposition of the uterus. Such conditions have been found frequently enough in the fœtus to explain the origin of congenital deviations, so that embryonal development is responsible, not alone for the normal position of the uterus, but likewise for a large proportion of malpositions.

The examinations of Schroeder are of the greatest interest. To determine the frequency of retroversioflexio in healthy women, and in women not suffering from pelvic symptoms, he examined 184 women six weeks postpartum, 82 other patients complaining of no pelvic symptoms, and 145 general cases in the internal medical clinic in Königsberg. His examinations of 411 patients included virgines intactæ, nulliparæ, and multiparæ. In 25 virgines intactæ without pelvic symptoms, he found a retroversioflexio ten times. In 40 nulliparæ without pelvic symptoms, he found 14 cases of retroversioflexio. Three virgines intactæ with pelvic symptoms furnished 1 case of retroversioflexio, while 5 times retroversioflexio was found in 13 nulliparæ suffering with some pelvic symptom, giving for 90 nulliparæ 30 cases, *i. e.* 33 per cent. of retroversioflexio.

One hundred and ninety-one multiparæ without pelvic symptoms furnished 42 cases of retroversioflexio, while 29 retrodeviations were found in 85 patients acknowledging some pelvic symptoms, making a total of 71 cases of retroversioflexio in 276 multiparæ, *i. e.* 25 per cent.

At the menopause 13 retroversioflexios were found in 38 patients without pelvic symptoms, while 4 cases were found in 7 women with pelvic symptoms, giving 17 retrodeviations in 45 patients, *i. e.* 37 per cent.

In these 411 women were found 18 per cent. of retroversions and 10 per cent. of retroflexions, giving a total of 28 per cent. In 303 patients without pelvic symptoms were 79 retrodeviations, 26 per cent. In 100 cases with symptoms were 39 retrodeviations, 36 per cent. It is to be mentioned that the symptoms were brought out only on special questioning.

It seems, therefore, that 25 per cent. of healthy women have retrodeviations of the uterus, of which two-thirds have retroversions, and one-third retroflexions. Of the 79 cases of retrodeviation without symptoms, 8 suffered from hysteria, 3 from neurasthenia, 4 from indefinite stomach symptoms, 3 from headache, and others from backache, dizziness, ischias, lumbago, etc. Of these 79 cases only 16 evidenced a more or less profuse menstruation, so that menorrhagia is no result of retroflexion.

Of 39 cases of retrodeviations with symptoms, 6 nulliparæ complained of some pain in the pelvis and back, with some disturbance (pain) during menstruation, 5 had shortened or painful folds of Douglas, 11 shortened, infiltrated, and painful parametria; 3 descended ovaries, and 5 descent of the anterior vaginal wall, giving 24 cases suffering from pain in the pelvis or back in whom causes other than the retrodeviation could be found.

This review is quite sufficient to establish the fact that congenital retrodeviations are very frequent, and that retroversioflexio constitutes a practically normal condition.

How large a proportion of those retrodeviations, found during pregnancy or after pregnancy or abortion, are such congenital retrodeviations every one can decide for himself.

The course involved in pregnancy is shown by the rare occurrence of retroflexio uteri gravidi incarcerata. Martin found in 24,000 gynecological patients 121 cases of retroflexio uteri gravidi, none of which caused decided annoyance. Of these, 94 came under observation with retroflexio uteri gravidi, while 27 became gravid after they had been under observation. All these cases are probably pregnancies in a uterus already retroflexed. The majority of such cases are not observed because practically no symptoms are present.

In the opinion of Küstner prolapse of the uterus results from a retroversioflexio, while Veit holds that prolapse of the vaginal wall is an important factor in pulling the uterus out of its normal position. When we consider how difficult it often is, in a vaginal hysterectomy, after opening the vesico-uterine plica, and after entering by incision into the sac of Douglas, to bring down the uterus, we may understand how improbable it is that the vaginal wall can affect the uterus as Veit believes. Only when the parametria at the sides of the cervix and uterus are incised do we make a decided impression upon the uterus.

On the other hand, if the view of Küstner be correct, the frequent occurrence of congenital retroversioflexio should be often followed and complicated by hysteroptosis, which, however, is not the case. Hysteroptosis has in its train symptoms which may be understood when we consider the annoyances associated with gastroenteroptosis, ren mobilis, etc. Above all, the predominant pathological element is œdema, not only of the uterus, but especially of the connective tissue constituting the parametria.

Retroversioflexio and hysteroptosis, though often combined, are separate affections. This distinction has a bearing also on the question of postpartum treatment. Too much stress is laid upon retrodeviation. Küstner advises an upright position within a few days after labor, believing that in this way, and through the consequent exercise given to the uterine ligaments, the normal position of the uterus is assured. Such a view leaves out of con-

sideration the all-important fact that involution includes not only a return of the uterus, but a return of all the pelvic structures and the pelvic connective tissue to a normal condition.

The indications for treatment, surgical and otherwise, are different for hysteroptosis and retrodeviations. Leaving out of consideration the interesting question of retroflexio fixata, and the peritoneal complications of retrodeviations, I summarize my views as follows: 1. Retroversioflexio *per se* is not a pathological condition. 2. The majority of retrodeviations are of congenital origin. Retroflexioversio is not an obstacle to the cure of pelvic affections. 3. Where retroversioflexio without peritoneal, tubal, or ovarian complications causes symptoms, an hysteroptosis must be taken into consideration, always bearing in mind the possibility of other physical states, especially gastroptosis, enteroptosis, ren mobilis. 4. Prolapsus vaginæ and cystocele, while often associated with retrodeviations, are independent affections. 5. Where retroversioflexio is accompanied by severe local symptoms, these, if not due to peritoneal, tubal, or ovarian complications, may be corrected in the vast majority of cases without surgical treatment.

127 East Sixty-first Street

TREATMENT OF TYPHOID FEVER.*

By BASIL M. TAYLOR, M.D.,
GREENSBURG, KY

The domain of medicine contains two great subjects: physiology and pathology. When nature puts into existence a being she aims at but one end, and that is to maintain the law of physiology.

Disease may hinder or even arrest this law, but the struggle is kept up until restoration or death. As we are coworkers with nature, we must have physiology as our guide or the result will be a failure.

The physician, then, who prescribes without this particular end in view is a menace to suffering humanity. His intentions may be good, but the physiological action of pills and capsules will not be changed to cover his mistakes.

Any disease that has a duration of two or three weeks tests the skill of the physician. The patient has but one stomach, and upon this organ falls the duty of absorbing medicine and liquids, and digesting the foods necessary for the nourishment of the patient. The mind and the muscles can rest, but the stomach and the heart must work or the struggle soon ceases. These are the two sentinels upon which depends the safety of the patient.

The patient must be congratulated if he has a physician who will aid these organs in their struggle, but he is to be pitied if the physician taxes them unduly in his efforts to cure typhoid fever. The treatment of any disease does not consist merely in getting a patient out of bed; that is only the foundation of the building, so to speak. There is more honor in keeping a man out of the fire than there is in dragging his charred remains from the flames. He is then out of the fire, it is true, but is not of much service to his family afterward.

Nature with her fixed laws is the attorney for the patient, and we are the judges to sit upon the case and allow no advantage to be taken by the ever-alert bacteria that inhabit the body and are constantly waiting for an opportunity to attack and devour when the vitality is lowered.

There are rules to guide us in the treatment of disease. Treat the patient and not the disease; keep in touch with nature and have a scientific reason for everything you do and say. treat the case as nature treats it and you will be nature's assistant. The constant irritation of the delicate mucous membrane of the stomach by medicines for two or three weeks may change a once healthy stomach into a diseased one that may end the patient's life. Injudicious feeding may cause an intestinal catarrh from which the patient may never recover. The responsibility of the physician in prolonged diseases is far greater than he realizes. It is no honor to make a "catch-all" out of a healthy stomach and bowels during an attack of typhoid fever, and make a physical wreck out of what was once a perfect type of physical manhood.

When we look over our record and see the number of lingering cases of typhoid fever, we may safely say that ninety per cent. of these cases would have progressed differently if we had treated the cases skilfully. We may nurse and feed the patient faultlessly, loving hands may smooth the pillow and make the bed easier, anxious friends may kindly remember, but one irritating and useless drug may defeat our plans and wreck the case.

Then whose is the fault? It is not the drug's; for pills and bullets are blind and wound friend and foe alike. You can claim the fault as your own. We must reason from cause to effect and from effect to cause, meet every indication with its corresponding remedy and give medicine for its effect. Routine feeding and prescribing are vicious practices. A drug that is indicated in the father may kill the son, though they lie side by side with the same disease. The sum total then is, know your patient.

As typhoid fever is a septic disease, we must favor elimination and assimilation. The toxins must pass out as rapidly as they are absorbed, but the system has enough to do to eliminate the toxins alone without the extra labor of eliminating undigested food and useless drugs.

The functions of the stomach are threefold—digestive, absorptive, and germicidal. The three work in harmony, and what impairs one impairs the other two. We frown upon the surgeon who tries to cleanse his wound and at the same time dresses it with a foul dressing, but we pat the physician on the back and label him a hero who feeds and stimulates a patient every three hours for six weeks or two months when the latter finally gets up in spite of his physician's efforts to the contrary.

When called to see a patient with typhoid fever, open the journal and examine his liabilities and assets. Is the patient apparently older than his age? If so, why? Is his pulse excited, weak, or strong? If so, why? Is he nauseated, full of aches and pains? If so, why? Is there gurgling in the right iliac fossa, and is his tongue foul? If so, why?

If there are these symptoms, be sure that you can wash your hands clean of their cause. There is no necessity for foul tongue, delirium, sick stomach, pains, headache, insomnia, high temperature, or weak pulse in typhoid fever. If we will but practise physiology instead of medicine, we shall avoid these.

When you get a fever patient in bed, give him a rest—I mean a rest from the soles of his feet to the crown of his head. There will be a drain on the system, a disturbance of the equilibrium between assimilation and waste. The patient lives on himself to a certain degree, and so we must minimize waste in every organ. The patient's mind must not be upon his business; if he has been irregular in his habits, we must at once establish a regularity; in fact, we must, as nearly as possible, reorganize his organic harmony and let each organ do its work.

Let us divide our patients into two classes: First,

*Read at the meeting of the Kentucky State Medical Society, Louisville, Ky., May 24, 1901.

those who have been healthy prior to the acute disease; second, those who have had some chronic disease for years. In the first class we have an opportunity to show our skill or put the patient into the second class for the next case of fever.

Patient "A" is in the first class. He is a perfect type of physical manhood. He had been complaining for a few days and had called at the doctor's office several times for medicine. He was given calomel for biliousness and quinine for malaria. His already inflamed bowels were irritated by the calomel and his liver wondered why it was dosed and stirred up for a trouble that lay ten or fifteen feet down the the alimentary canal and over which it had no control. The patient grew worse, and after a chill, a restless night with aches and pains, he sent for the physician. His liver, irritated by the calomel, had poured out a lot of bile and he had been vomiting it into the slop jar for several hours. The sight of so much "bile on his stomach" proved to the doctor that the patient was very bilious and must have more calomel. (His physician failed to realize that the slop jar was more bilious than his patient.) The calomel was repeated and so were the deleterious effects of the drug.

The patient had been taking medicine irritating to his stomach and had been eating indiscriminately since the first symptoms of his trouble, and the chill, high fever, and headache tell us of the fact. If the physician recognizes typhoid fever, he at once informs the nurse that he must begin to nourish and stimulate the patient to tide him over a long and dangerous illness. He directs the patient to take a glass of milk or a bowl of soup every three hours, and if the pulse is a little accelerated from the action of the toxins, he mistakes this for an indication for stimulants and directs him to take a tablespoonful of whiskey every three hours until he returns. How many of us have ever been guilty of this mistake? A link in the trinity has already been broken, and we make the separation greater and perhaps permanent by over-feeding and stimulants. A healthy stomach has enough to do to digest three meals a day, but when the patient takes typhoid fever the stomach needs a rest. Yet we cause it to work constantly by giving food every three hours. This is kept up for a week or more until the patient begins to vomit. We have been pouring antiseptics and septics into the man day and night, disturbing his sleep to give him food, so that if he dies the family and we can say that everything was done for him that could be done! This is true in one sense of the word. No wonder it takes him weeks and months to recover. The doctor and the disease make a combination disastrous to any patient, though he have a constitution of iron. The temperature is running to 104° or 105°; the man's expression is dull; he is delirious; sordes are upon his teeth; he sleeps with coma vigil; his pulse is weak; there is diarrhœa; there is gurgling in the right iliac fossa. We have now got our patient into what is called the typhoid state—a state that we ought to be ashamed of.

Each glass of milk gives impetus to the trouble, for it passes into the bowels undigested and the patient poisons himself hourly. Now about the whiskey you have been giving. Here is another fatal mistake. Why? Because the pulse laboring under the poison is accelerated and you mistake this for weakness or an indication for stimulants. The heart needs a rest instead of stimulation. Stimulation causes overwork and exhaustion at the time when good circulation is most needed. Let the heart alone; it knows its own business better than we do. It is useless and disastrous to stimulate a weak heart muscle.

Now for treatment of case "A." The best rule is if you don't know just what to give, don't give anything. Guess work in medicine is bad practice. There already exists an inflammation in the bowels and it is unsurgical to cause severe peristalsis by giving a purgative—the giving of calomel is then unsurgical. If the patient is nauseated, I withdraw all food until his stomach is in a condition to digest it. Then I feed him three times a day and give just such food as he can digest perfectly. If the patient is not hungry at meal-time, I direct him to wait until he has an appetite. If the stomach is taken care of, this waiting will not occur very often. His food consists of beef tea, beefsteak, scraped to a pulp and heated gently, cracker crumbs rolled fine, eggs, either raw or cooked, and soups in small quantities and highly nutritious form. I never allow the patient to eat anything that he is required to masticate, yet always prepare food so that it needs to be mixed with the saliva. Then his stomach will digest perfectly the food, and the patient will be nourished and the germs starved, while the stomach will get the needed rest. There will be no self-poisoning from decomposed food that passes out of the stomach. Orange or lemon juice will be grateful to the patient and will do no harm.

When the temperature runs over 100°, I use as an antipyretic, antifebrin, or give a tepid bath for twenty or thirty minutes. About two or three doses a day and one at bedtime will keep the temperature down and will make the patient more comfortable. I prefer the bath, however, when it can be given. The patient is bathed two or three times a day with tepid water for about twenty minutes. If the patient is a little restless at night I give him a sedative; bromides act nicely and leave no bad after-effects. As a rule, the patient will rest well after a few nights, if the nurse does not disturb him every few hours during the night to give medicine and food. This is a point that I wish to emphasize, "Avoid disturbing a patient during his sleep." Rest is essential to health, and of course a sick man needs it; let him sleep until he awakes of his own accord.

If the tongue is dry, it shows a morbid condition of the stomach and the patient must be watched with care. I let the patient drink all the water his stomach can absorb.

It is next to impossible to give antiseptics enough to render sterile the alimentary canal; furthermore, most antiseptics are gastric irritants and their continued use is dangerous.

If there is much decomposition, I use small doses of some saline cathartic until the canal is cleansed, and then I use tincture of iodine and carbolic acid in small doses until their physiological effects are manifested.

I keep the mouth clean and let the patient chew tolu for a few minutes during the day. In my efforts to guard the stomach, I do not forget the colon and rectum; I irrigate the colon three times a day with warm water, and if there is catarrh, I add to the water concentrated extract of pinus canadensis, and then at night inject into the sigmoid flexure a mixture of almond oil, bismuth, and iodoform. This will relieve the catarrh and prevent the lower bowel from absorbing the putrefactive material, and thus help to relieve the system of what plays an important part in the production of the typhoid state.

If water is not taken in sufficient quantities by the stomach, I inject about a quart into the colon and leave it for absorption

Case "B." This class of cases gives us much more trouble, because we begin the struggle at a disad-

vantage, but we have an opportunity to use the same care and judgment as in Case "A." Most chronic diseases are in the lungs, kidneys, heart, or alimentary canal. I have seen consumptives pass through an attack of typhoid fever as easily as robust patients, but dyspeptics are a source of worry to the physician. We must watch the digestion with especial care. If there is myasthenia with fermentation, we must give a small amount of food, easily digestible and slow to ferment. The white of an egg given raw with pepsin and hydrochloric acid suits this class of patients: it is digested and leaves the stomach in about an hour and a half, thus giving that weak organ much-needed rest. Do not give milk to a patient with gastric catarrh or myasthenia; milk given every three or four hours will kill more patients than the fever. Treat the stomach and feed it just as you would if the diseased stomach was the only trouble the patient had. The colon is irrigated and the baths are used as detailed in case "A."

In the treatment of your cases let your motto be, "Remember the stomach first, the colon next."

Results of Serum-Therapy and Protective Inoculation for Dysentery.—K. Shiga obtains a serum, as in typhoid fever, cholera, or the plague, from a perfectly immune animal, the horse or ass being preferred. The method of producing immunity in the animal is as follows: A slant agar culture of the bacillus which has been in the incubator for twenty-four hours is scraped off and ground up in an agate mortar; to this is added physiological salt solution, and the mixture is kept for twenty minutes at a temperature of 50° to 60° C. A small dose of this mixture is used for the first subcutaneous injection. The dose is increased from time to time until a certain degree of immunity is established, after which intravenous injection is used. After a high degree of immunity is obtained, the blood is withdrawn three weeks after the last injection, and the serum is then obtained. To this serum, carbolic acid in the proportion of five per cent. is added. Before using serum on a patient, its strength should be first tested on an animal. The method of using the serum is similar to that in other serum treatment. The side of the chest is preferred as the seat of injection. The amount injected in the mild form is from 6 to 10 c.c. while from 15 to 20 c.c. is used in the serious form. The serum is readily absorbed within one or two hours, and the point of injection does not usually show any change. There is not very often an eruption following the injection. There are sometimes pains in the joints, and at times these are accompanied by muscular pain. The results of serum treatment are far more favorable than those of medicinal treatment. Even in the most favorable results of the latter the death rate is twice that of the former. The following medicines were used in addition to the serum treatment: calomel or castor-oil was first used to cleanse the bowels, and an enema of salt solution or soda water was afterward used repeatedly. Besides these, dilute hydrochloric acid lemonade, claret, and some alkaline remedies were used.—*The Sei-I-Kwai Medical Journal.*

The Pathogenesis of Chronic Gastric Ulcer.—W. v. Yzeren reports a series of unusually elaborate experiments he carried out on rabbits, and which seem to justify Talma's theory that gastric spasm is the underlying cause of chronic peptic ulcer. By cutting the vagi of rabbits below the diaphragm, the author found that he could produce ulcers which in almost every particular corresponded to those found in human stomachs. This ulceration appeared several days after the operation, and showed no tendency to spontaneous healing; there was usually but one ulcer, and this was situated in the pyloric region or close to the lesser curvature. The ulceration was preceded by necrosis of the mucosa, while the structures more remote from the pylorus were not affected. Gastro-enterostomy and incision of the pylorus seemed to prevent the formation of the ulcers, or, at least, to postpone it. After the operation, the stomach was distinctly harder on palpation, indicating a condition of spasm, and this, the author thinks, is the important part of his observation. Spasm of the gastric musculature produces anæmia of the mucosa, which results in necrosis; and as the muscle is thickest about the pylorus, it is here that the lesion is situated. A similar condition of spasm undoubtedly occurs in the human stomach, though the rationale of its causation is still unexplained, and the result is chronic ulcer. Sometimes such a spasm may be recognized by palpation, but usually the rectus is also contracted and prevents this, but an important diagnostic sign is the detection of intermittent retention. Any remedial measure, to be effective, must prevent the occurrence of the spasm, and this, the author believes, is best effected by his method of extra-mucous incision of the pylorus. This consists in dividing the substance of the pylorus down to the submucosa, which is left intact; if done near the lesser curvature, the bleeding is very slight, and the wound does not require suture.—*Zeitschrift für klinische Medicin.*

The Best Method of Removing the Tonsils.—Macleod Yearsley advocates the removal of the tonsils by enucleation, and gives the following directions for the performance of the operation: The patient is put under general anæsthesia, and the mouth is held widely open by a gag. The tonsil is seized by a pair of forceps and pulled out as far as possible from its bed. A pair of forceps with a large grasp is required, as the tonsil is very friable and may tear away from the instrument when least expected. He has found a pair of ordinary vulsellum forceps, slightly curved, to be most useful. Holding the tonsil up and out with the left hand, the operator snips through the mucous membrane at its lower border with a pair of scissors curved on the flat. Then with a flat or curved director he undermines the tonsil at this point and frees it. The gland is then shelled out from below upward, the fingernail furnishing the most ready and efficient instrument for this purpose. When the tonsil is much bound down and adherent the operation is often difficult, and requires patience, but by working carefully and methodically, aided by good sponging by the anæsthetist or an assistant, the tonsil can be systematically and thoroughly removed in any case. When the gland has been completely shelled out, the finger should explore the space left, and any remaining shreds of tonsillar tissue should be removed with a sharp spoon.—*Medical Times and Hospital Gazette.*

Aneurysm of the Thoracic Aorta of Traumatic Origin; Treatment by Introduction of Wire and Electricity.—De Forest Willard, in describing the technique of this operation, states that the size of the wire should be graduated to the caliber of the needle, whose bore should be perfectly smooth. Size 27 to 30 is probably best. He sees no practical difference between gold, silver, and platinum wire. The amount of wire should be regulated by the size of the aneurysm, as it is to form a skeleton for a clot. The wire should reach all parts of the sac and thus should be previously so wound as to coil in all directions. The tissues must be protected from the galvanism. The best insulation of the needle is afforded by French lacquer or varnish, set by heat. This can be sterilized by dry heat up to 300°. A long veterinary hypodermic needle is better than a trocar and cannula, for the wire can be pushed half-way into the needle before the puncture is made, and assists in controlling primary hemorrhage. Permanent cures are few; still, in one-half of the cases reported life was extended and comfort increased. The results stand as follows: Ten patients re-

ceived positive benefit, one was unimproved, and the others died within a year. This method seems to offer a greater hope of success than any other now known.—*University of Pennsylvania Medical Bulletin.*

Diagnosis of Mild and Irregular Smallpox as Found in the Present Outbreak in the United States.—Heman Spalding describes cases which have come under his observation in the past two years. While the typical case is always present in epidemics there are many deviations. He classifies the cases seen in two outbreaks of the disease in the Chicago Isolation Hospital under the heads of the hemorrhagic form, the confluent, semi-confluent, severe discrete, mild discrete and a form modified by vaccination; he also recognizes a form of smallpox without eruption. An absolute diagnosis cannot be made before the eruptive stage, but in all the cases, however mild, there was a general conformity to the history and course of a typical case. In making a diagnosis of variola, it must be remembered that there are always some prodromal symptoms, and that the patient will feel better when the eruption appears. The early appearance of the eruption is to be looked for on the vascular parts, and one must not depend on finding umbilications, as they are often absent in mild cases. The deep lesion of smallpox is distinguished from chickenpox, the latter being superficial. It is also to be remembered that an irregular mild case, while it gives immunity, can yet convey typical confluent or hemorrhagic smallpox to others.—*Department of Health, City of Chicago.*

The Complications and Degenerations of Fibroid Tumors of the Uterus, as Bearing Upon the Treatment of these Growths.—Charles P. Noble takes issue with the teaching that fibromata of the uterus rarely causes grave symptoms, and tend to undergo spontaneous cure after the menopause. An examination of 218 cases operated on by the author shows that the complications were such as to lead in 66, to inevitable death; to threaten life in 25, and to leave 30 of the remaining patients permanent invalids. The menopause may not bring any improvement, and even if it should, necrosis may occur subsequently. Twelve patients were over fifty when they sought relief from sufferings that should have been symptomatically cured, according to the teachings. In women with fibroids the menopause is delayed from three to ten years. The mortality of hysterectomy and myomectomy for fibroids varies from two to ten per cent., that of the tumors their degenerations and complications are upward of thirty-three and one-third per cent. Early interference not only greatly lessens the mortality, but shortens convalescence and does away with the prolonged invalidism which is otherwise unavoidable.—*British Gynecological Society Reports.*

Cæsarean Section in Eclampsia.—A. Sippel says that every case of eclampsia is a situation of utmost gravity, and demands unremitting watchfulness. As soon as delivery is possible by version or instrumentally, it should be undertaken without awaiting the development of serious complications. If these do arise, if the temperature goes up, the pulse remains small and rapid in the intervals between the seizures, and the cyanosis persists, indicating impaired respiration and circulation, while the urine is much diminished, and the pharynx filled with masses of mucus, delivery is urgently required, and should be performed in whatever way will prove most speedy, safe and least hazardous to the child if it is viable. In addition to the usual vaginal methods by dilatation and incision, the abdominal route must be kept in mind and Cæsarean section is often the most rational method of procedure; while the conditions requiring it may not arise frequently, still the necessity for rapid and energetic therapy, which it appears will be the future treatment of eclampsia, may sometimes justify the assumption of more than ordinary risks, and this operation deserves a place in the list of measures available.—*Monatsschrift fur Geburtshulfe und Gynakologie.*

A Case Resembling Morbus Cæruleus, Probably Due to a Dusting Powder Containing Acetanilid.—Samuel E. Earp reports the case of an infant one month old, whose entire body was of a bluish-gray appearance, the lips and tongue being nearly black, the condition was accompanied by mental dulness, cold skin, abnormally slow respiration, but no evidences of dyspnœa. A week previous there had been a mild attack of diarrhœa, and the buttocks were raw from contact with the discharges. The blue appearance lasted several days. There had been no drugs given which could have produced cyanosis, but the buttocks had been dusted with equal parts of boric acid and acetanilid. The author concludes that the cyanotic condition was due to the acetanilid poisoning, excluding morbus cæruleus on account of absence of congenital heart or lung disease, and atelectasis, because at the age of one month there had been no previous evidences of the above condition. The child at the time of the report was two years old, and there had been no recurrence and no symptoms of the former attack. There was no luetic history.—*Pediatrics.*

The Home Treatment of Tuberculosis.—Robert H. Babcock believes that the general practitioner depends too much on medicinal therapy in treating tuberculosis. The successful treatment of pulmonary tuberculosis lies in the hygiene of the patient's daily life, such as superalimentation, sojourn in the open air, hydrotherapy and careful regulation of daily life. These requirements can be obtained at home. Regarding nutrition, the essentials are food at short intervals, of a kind easily digested and assimilated, and that is most nutritious in the least bulk. The tuberculous patient should remain at absolute rest in the open air when he has a temperature above 99°, or when exercise increases the temperature. This obtains in all weather, care being taken, however, to protect him against cold. A bath, followed by vigorous friction, should be given every morning, and the temperature of the bath should be decreased gradually until the patient can stand a cold douche. The daily regime must be systematically observed, the physician seeing the patient often enough to control him.—*Illinois Medical Journal.*

The Fate of Congenitally Syphilitic Children.—J. Karcher investigated the further history of all the hereditary-syphilitics discharged as cured from the children's hospital of Basle during 1876-1896. Those were thirty-one in number, and it was possible to obtain information concerning sixteen. Six died in infancy, and four were found past the age of puberty and perfectly well. Another patient was healthy and employed in a factory, though no details as to his condition could be obtained. Five children were found who suffered from subsequent tubercular infection. The author concludes that the prognosis in cases of this sort is not as hopeless as it is usually considered, and that a thorough course of inunctions is sufficient, not only to cure the immediate manifestations, but also to offer good prospects for the future health of hereditary infantile syphilitics.—*Correspondenz-Blatt fur Schweizer Aerzte.*

Agglutination of the Blood in Malaria.—During the course of laboratory experimentation, D. La Monaco and L. Panichi discovered that if a drop of blood from one malarial patient be added to a drop from another malarial patient, the erythrocytes become agglutinated to a greater or less extent. Normal blood does not thus affect other normal blood, but malarial blood does produce this same phenomenon in normal blood. The authors describe the processes by means of which they confirmed the discovery. Agglutination is not peculiar to malarial fever, but none the less it may be of great use in the study of the course and progress of the disease and of its treatment.—*Il Policlinico.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 Fifth Avenue.

New York, September 28, 1901

ALCOHOLISM AND TUBERCULOSIS.

THE connection between alcoholism and tuberculosis has been and is still the cause of a wide diversity of opinion among medical men, and has given rise to copious discussion.

The physicians of a time gone by were generally implicit believers that alcohol was antagonistic to tuberculosis, and carried this belief into practice by dosing their patients with heroic quantities of spirit. Gradually, however, a change has come, leading to the rejection of this once popular view, and now many of the medical profession hold not only that alcohol is contraindicated as a therapeutic remedy in phthisical cases, but that the habit of alcoholism strongly predisposes to the contraction and propagation of tuberculosis.

Dr. Brouardel of Paris, in his eloquent address delivered before the Congress on Tuberculosis, recently held in London, dwelt with special emphasis on this phase of the matter, and declared it to be his conviction that the relationship between alcoholism and consumption was very close. He said in part, "Alcoholism is the most potent factor in propagating tuberculosis. The strongest man who has once taken to drink is powerless against it."

Baudran of Beauvais has shown that the mortality from tuberculosis and that from alcoholism are nearly identical. Dr. Brouardel also drew attention to a mistake made too easily in the different countries of the world by ministers who have charge of the financial department of the State. They like to calculate the sum the State gets from the duty on alcohol, but they should deduct from it the cost to the community of the family of the ruined drunkard, his degenerate, infirm, scrofulous, and epileptic children, who must have shelter. The invasion of alcoholism ought to be regarded by everyone as a public danger, and this principle, the truth of which is incontestable, should be inculcated into the masses, that the future of the world may be in the hands of the temperate.

In the *Edinburgh Medical Journal* for September is an article by Dr. Kelynack of Manchester, which follows the same line of argument. Dr. Kelynack puts the position, as regards the aspects from which the question is viewed by present-day scientific men, as follows: (1) That alcoholism is antagonistic to tuberculosis; (2) that alcoholism bears no special relationship to tuberculosis; (3) that alcoholism definitely predisposes to tuberculosis; and he gives the views of well-known physicians of various countries bearing on the point at issue.

Flint used alcohol freely, that is from 6 oz. to a pint of spirit daily, and appears to have had a firm belief in its efficiency in the treatment of tuberculosis. Chartens, writing in 1877, concerning the administration of whiskey to phthisical patients, says: "In private practice I order it to be taken ad libitum." Hermann Weber expressed himself in like terms, but Bell of New York as far back as 1859 opposed the view, then generally current, of the beneficial influence of large quantities of spirit on the course of pulmonary tuberculosis.

That alcholism definitely predisposes to tuberculosis has of recent years received much support, and the theory would appear to be gaining ground at a rapid rate. Hector Mackenzie believes that alcoholism must be regarded as a powerful predisposing cause of tuberculosis. Osler refers to the subject thus: "It was formerly thought that alcohol was in some way antagonistic to tuberculous disease, but the observations of late years indicate clearly that the reverse is the case, and that chronic drinkers are much more liable to both acute and pulmonary tuberculosis. It is probably altogether a question of altered tissue soil, alcohol lowering the vitality, and enabling the bacilli more readily to develop and grow." Dr. Kelynack himself says that, having had exceptional opportunities of studying large numbers of cases among workhouse and hospital patients, he is convinced that the public house or saloon must be considered as one of the most serious obstacles to the speedy and effectual stamping out of tuberculosis.

Italians, Germans, and physicians of other countries who have studied the effects of alcoholism in connection with tuberculosis have arrived at similar conclusions. It is further contended by some that, in addition to a general impairment of vitality and pernicious environment, there is a special prejudical influence arising from the action of the alcohol and its associates. This, as Dr. Kelynack points out, is very hard to prove, and at present, and until investigations have more clearly elucidated the matter, we must rest content with the knowledge already gained—that alcohol exerts little or no beneficial influence on the course of tuberculosis, but that on the contrary it tends to predispose to the malady those who consume it to any extent. Indirectly, of course, the fact is undeniable that alcohol is a prominent cause of tuberculosis, by lowering the vitality of its subjects, by inducing poverty and necessitating life in unhealthy surroundings, by causing degeneration of the individual and offspring, and by these means rendering the race more susceptible and prone to infection. Suppression of alcoholism should go hand in hand with that of tuberculosis.

RHEUMATIC CHOREA.

ALTHOUGH it has long been thought that some relation exists between chorea and rheumatism, and the belief is now growing that the former is an acute infectious disease, while a number of investigators have regarded microorganisms as the cause of the latter, the etiology of chorea is yet shrouded in obscurity. In this connection the important fact must be borne in mind that not all forms of involuntary, incoordinate movements are choreic, nor all

forms of articular pain, swelling, and discoloration rheumatic.

At a meeting of the Medical Society of London, Dr. Leonard Guthrie presented a communication (*British Medical Journal*, May 18, 1901) in which he considered ordinary or Sydenham's chorea as a rheumatic manifestation and not as a disease in itself. In his opinion, shock from any cause, whether produced by injury, chill, exposure, or emotion—such as fright—lowers vitality and favors the action of the diplococcus of rheumatism. When chorea ensues there is doubtless some peculiar instability and weakness of the nervous motor elements as well. Two main varieties of chorea were recognized, (a) sthenic or explosive and (b) asthenic or pseudo-paralytic. Each of these may be either severe or mild.

Severe cases of sthenic chorea are characterized by spontaneous, uncontrollable, conflicting movements, increased by efforts at voluntary motion and when the patient is under observation. The milder cases include those (1) in which spontaneous movements cease during rest, but are excited by voluntary motion and by observation; (2) in which spontaneous movements can be controlled by an effort of the will, although the effort results in rigidity of the limbs—extreme incoordination or attempted voluntary action is common in these; (3) residual chorea, in which the symptoms continue, although the complaint seems cured, for spontaneous movements cease and voluntary motions can be performed without ataxia and rigidity when the child makes an effort of the will. The duration of severe sthenic cases seldom exceeds two or three weeks. Sometimes one or other of the subvarieties then makes its appearance, but more commonly severe sthenic cases become equally severely asthenic in character. Sometimes mixed cases in which both types prevail are encountered.

In cases of severe asthenic chorea all movements cease and the patient appears paralyzed from head to foot. Rapid emaciation is the rule. Mania or dementia sometimes ensues and complete mutism lasting many weeks is common. In milder cases movements are also absent and the patient seems to be paralyzed in one or more limbs. Mild cases sometimes become severe. Severe asthenic chorea rarely becomes sthenic in type.

Severe sthenic cases should be treated by absolute rest in bed, protection from injury, and in some cases by restraint of movement by splints and bandages. Chloral hydrate and bromides are the best remedies. Other sedatives also are useful. Severe asthenic cases require rest in bed, abundant diet, stimulants and tonics, massage, and galvanism.

The methods employed in milder sthenic cases include (1) suggestion; (2) suggestion with passive movements; (3) suggestion with voluntary movements under guidance; (4) voluntary movements and exercises without guidance. Incoordination may be treated, according to Frenkel's system as employed in cases of locomotor ataxia, by exercises and various toys and games calculated to aid precision in movement.

Treatment by suggestion and encouragement of voluntary action is serviceable also in cases of asthenic chorea. Arsenic in ordinary doses is useful in many cases, but the employment of heroic doses is useless, unjustifiable, and dangerous.

THE UNSATISFACTORY POSITION OF THE ARMY SURGEON.

THE *Army and Navy Journal*, August 24, prints an editorial, which appeared in this journal on August 10, bearing on the above matter, and comments upon the same. While deprecating the assertion made in the MEDICAL RECORD that "Congress seemed to take an especial delight in degrading the Medical Department" as somewhat unnecessarily harsh, nevertheless it frankly admits the cogency of the argument, in so far as the statement that the Medical Corps has not been given its just dues is concerned. The reason assigned by the *Army and Navy Journal* for this ignoring of the Medical Department—that its members have refrained from self-assertion, and that the medical profession as a whole has always exhibited a supreme indifference to politics, is undoubtedly the right one. The old saying that "God helps those who help themselves" is to the point in this case, and medical men would do well to put it into practice.

It would be hopeless to expect that the medical profession will ever be able to push its claims with the same persistence and success as that of the law. A lawyer is trained to this style of warfare; indeed, the art of lobbying may be termed a branch of his profession, and he can give time and brains to the perfecting of the science which would be in the nature of things impossible to the physician. But although the medical man may never hope to shine as a lobbyist, he may still, by organization and by exerting himself in the fields of politics, show that he is not altogether the negligible quantity which Congress, judging from its shabby treatment, would appear to regard him.

The medical man, whether in the army or in civil life, may rest assured that unless he takes such steps, his interests will be disregarded in the future as they have been in the past. Effective organization and a steady advocacy of its claims are the only weapons by which the medical profession can hope to fight a successful battle for its rights.

A New French Hospital is to be built by the French Benevolent Society of this city during the coming twelvemonth. It will be on Thirty-fourth Street near Tenth Avenue, with a frontage of eighty-four feet, and a depth of ninety-eight feet nine inches. It will be seven stories in height, built of brick and limestone, and practically fireproof. A novel feature will be an isolating ward for tuberculous patients on the top floor. The kitchen and laundry will also be on this floor. Another feature will be the number of sun parlors. Each ward will have a sun parlor of its own in the rear of the building, thus allowing the patients of the various wards to enjoy the sunlight without coming together. A large roof garden, attractively furnished, will surmount the whole. The floors will be reached by stone and iron staircases and a complete system of electric elevators. Mosaic and tiled floors will be used throughout the building. The furniture in all of the wards will be of glass and iron. The system of bathrooms and of general drainage will be of the most approved pattern. The French Government has contributed $20,000 together with a valuable Gobelin tapestry to the hospital fund. The tapestry is said to be the finest of its kind in America, and is valued at $50,000. It will be sold for the benefit of the society.

News of the Week.

Persistence of Yellow Fever Infection on Shipboard.—A steamer arrived a week ago at Santiago, six days out from Jacksonville, with three cases of yellow fever on board. The vessel left Progreso six weeks ago and arrived at New York with one case of fever on board. The man died in the harbor, and the ship was disinfected. The steamer left New York in apparently clean condition, but the captain's wife was taken ill soon after leaving this port and died while on the way from New York to Jacksonville. One man died the day the ship arrived at Santiago, and the autopsy showed plainly that he had been suffering from yellow fever. The crew was removed to the yellow fever hospital, which is situated on an island two miles from the city. The steamer was fumigated and held in quarantine in the lower bay, and in the course of a few days eight new cases of the disease developed among the crew.

The Latest Fashion in Superstition is reading of the fate in the soles of the feet, which is said to be crowding out palmistry. The new science may be appropriately called solecism.

Dr. T. S. Dedrick of the Peary Arctic Expedition resigned his position as surgeon to the expedition last August, in consequence of a disagreement with Lieutenant Peary, and started to return on the *Erik*, with the Peary Relief Expedition. At Etah, on the shore of Smith Sound, he suddenly left the vessel, announcing his intention to remain among the Esquimaux at Etah or Anaritok. Every effort was made to induce him to return with the party, but he persisted in his refusal, in spite of all arguments, and of Dr. Cook's warning that to remain alone in the Arctic region through the long winter night might be attended with serious results for him, particularly in regard to his mental condition. It is thought by some that his staying behind was due to an unwillingness to leave the party without medical help in case of need; others believe that his strange action can be accounted for only by some mental aberration.

The Second International Congress of Life Insurance Examiners was held in Amsterdam, September 23-26. Delegates were in attendance from nearly every country of Europe, from Japan, Brazil, Canada, and the United States. Among the subjects discussed in their relation to life insurance were albuminuria, glycosuria, syphilis, arteriosclerosis, alcoholism, tremor, appendicitis, hernia, middle-ear disease, ocular affections, diseases of the skin, wounds, and prolonged residence in tropical countries.

The Plague.—Seven cases of what is believed to be bubonic plague were discovered at Naples on Wednesday of this week. The government has ordered that energetic measures be taken to prevent the spread of the disease, and the authorities have sent to Paris for a quantity of plague serum, and are circulating leaflets giving information as to the measures necessary to be taken in the way of personal prophylaxis. Three of the persons attacked had already died when the suspicions of the health authorities as to the nature of the disease were aroused. The annual increase in the number of plague cases in Bombay has begun. During the first week of September the total number of deaths reported from this cause was 4,822, and during the second week this number rose to 6,386. These are the returns for all India, but most of the deaths were in Bombay Presidency.

The Spitting Evil in Boston. Six offenders were fined $5 each last Saturday, in a Charlestown court, for spitting on the floor of elevated railroad cars.

Dr. Nelson H. Henry of this city will, it is reported shortly be appointed Adjutant-General by Governor Odell. Dr. Henry is at present Assemblyman for the Fifth New York City District. He was connected with the medical department of the National Guard almost continuously from 1883 to 1898. He was appointed Assistant Surgeon of the grade of First Lieutenant, Twelfth Regiment, on March 16, 1883; Captain and Assistant-Surgeon on May 21, 1884; Surgeon with the rank of Major on June 23, 1888; Assistant Surgeon-General, S. N. Y., with the rank of Colonel on April 8, 1893; was honorably discharged on April 25, 1895; was made Assistant Surgeon-General, S. N. Y., with the rank of Colonel on March 29, 1897; Surgeon National Guard with the rank of Colonel on May 28, 1898, and Major and Chief Surgeon of Division United States Volunteers on July 8, 1898, to September 24, 1898 (Spanish war service).

The Rockland County (N. Y.) Medical Association.—On September 6, the members of the Fifth District Branch of the New York State Medical Association met at Nyack and organized a county association by the adoption of by-laws and the election of the following officers: *President*, Dr. Gerritt Blauvelt of Nyack; *Vice-President*, Dr. D. B. Van Wagenen of Suffern; *Secretary and Treasurer*, Dr. N. B. Bayley of Haverstraw; *Fellow*, Dr. S. W. S. Toms of Nyack; *Alternate*, Dr. Charles D. Kline of Nyack. Addresses were made by Drs. John A. Wyeth, Edmund L. Cocks, C. E. Denison, and J. W. S. Gouley of New York, Milton C. Connor of Middletown, and C. S. Payne of Liberty.

Civil Service Examinations.—The United States Civil Service Commission announces an examination to be held at various places throughout the United States on October 22, for the position of physician in the Indian service. Candidates must be between twenty-five and fifty-five years of age. The vacancy now existing is at the White Earth Agency, Minnesota, the salary attached to the position being $900 a year. There will also be an examination on October 29 and 30 for the position of Assistant Surgeon at the Freedmen's Hospital, Washington. The salary is $1,000 to $1,500 per annum. Although the examination is open to American citizens of any race, the practice of the Department is to appoint to vacancies in the Freedmen's Hospital only colored physicians if any such are eligible. Those desiring to compete in either of these examinations may obtain all needed information by applying to the United States Civil Service Commission, Washington, D. C., for application forms 304 and 375.

A French Commission for the Study of Yellow Fever.—A sum of 100,000 francs has been appropriated by the French Government to pay the expenses of an expedition to be sent to Brazil under the direction of the Pasteur Institute, for the purpose of studying yellow fever. The etiology and pathology of the disease will be the special subjects of the commission's investigations.

A Long Service as Ship's Surgeon.—Dr. Lloyd Parker of the American Line Steamer *St. Louis* will celebrate next week, upon his arrival at Southampton, the completion of his five hundredth trip across the Atlantic. He has been sailing with the company (originally the Inman Line) for twenty-one years, and in that time has traveled about 1,600,000 miles.

Philadelphia County Medical Society.—The Northern Branch of the Philadelphia County Medical Society was organized on September 19, Dr. Albert M. Eaton being elected permanent chairman, and Dr. R. L. Pitfield, clerk. Forty-seven members were enrolled at the meeting. To be eligible for membership in the local branch, membership in the parent society must first be acquired. It is intended that the membership of the Northern Branch shall be constituted of physicians residing between the Delaware and Schuylkill Rivers, and Fairmount Avenue and Wingohocking Street. Meetings are to be held monthly. The formation of a Southern Branch is in contemplation.

Dr. Lusk Exonerated.—The indictment found by the Queens County Grand Jury, last spring, against Dr. Obed L. Lusk, chief sanitary inspector of the Borough of Queens, charging neglect of duty, was dismissed a few days ago, the charges on which it was based not having been sustained. The indictment was found in connection with the death of a man from smallpox. The body was not removed for several days, and it was alleged that the delay was due to Dr. Lusk.

The Southwestern Tri-State Medical Society.—The second annual meeting of this society, membership in which is divided between Texas and Oklahoma and Indian Territories, will be held in Dallas on October 1 and 2. The program contains twenty-one titles, exclusive of the president's address. The president of the society is Dr. H. K. Leake, and the secretary and treasurer Dr. S. E. Milliken, both of Dallas.

No Poison on Czolgosz's Bullets.—City Chemist Hill of Buffalo and Dr. H. G. Matzinger, who were charged with a search for poison in the pistol used by the assassin of the President, have reported that the most careful bacteriological and chemical examination of the bullets, cartridges, and revolver has revealed no traces whatever of poison.

The Census of New York Physicians.—The Medical Directory of New York, New Jersey, and Connecticut, recently published, contains the names of 12,644 physicians, of whom 10,112 are in the State of New York, 1,472 in New Jersey, and 1,060 in Connecticut. Of the 10,112 names in New York State, 3,991 are credited to the Boroughs of Manhattan and The Bronx. The total number of physicians in all the boroughs of Greater New York is 5,579.

An Eclectic Hospital Incorporated.—The Cosmopolitan Hospital Society has been incorporated at Albany, "to maintain in New York City a hospital wherein the method of treating the sick shall be according to the Eclectic School." Among the directors are A. Stephen Aaronstamm of Brooklyn, Dr. Henry J. Doll, Dr. Meyer Wolff, Dr. Alfred W. Herzog, and Dr. Jacob Oshlag.

Disease in Alaska. The Rev. Father René, in charge of the Catholic missions in Alaska, reports that epidemic disease has caused a terrible loss of life among the Indians of the lower Yukon. He estimates that the deaths have numbered more than 4,000, the aged suffering especially. The disease appears to have been influenza, in its abdominal form chiefly.

State Aided Hospitals in Pennsylvania. The following are the amounts, we learn from the *Maryland Medical Journal*, given by the State of Pennsylvania to various hospitals in Philadelphia and elsewhere: The Medico-Chirurgical Hospital gets $100,000; the Free Hospital for Poor Consumptives, $110,000; the Medical Department of Western Pennsylvania Hospital, $100,000; University of Pennsylvania, $25,000; University of Pennsylvania Hospital, $58,000; Taylor Hospital, $15,000; Titusville Hospital, Jewish Hospital (Philadelphia), St. Joseph's Hospital, $10,000 each, and smaller appropriations to several other medical institutions.

Prosecution of Milk Dealers.—The State has undertaken the prosecution of certain manufacturers of condensed milk for selling or otherwise disposing of bad milk. Under the State laws dealers and makers are forbidden to dispose of cans that are hermetically sealed, unless each has upon it a label showing both the name of the maker and the brand of the milk. The charge is that some of the companies, although they do not sell bad milk directly to consumers, dispose of it to dealers, who in turn get rid of it either in unlabeled cans or in receptacles on which they have placed new labels of their own. The companies claim that they did not sell sour milk to dealers, but only to bakers who prefer it to fresh milk for bread making.

Dr. Presley M. Rixey, Medical Inspector in the Navy, and the late President's family physician, will be appointed by President Roosevelt Surgeon-General of the Navy, upon the expiration of Dr. Van Reypen's term of service in December next. Dr. Rixey was born in Virginia, and was appointed assistant surgeon in the Navy in January, 1874. He was selected as the President's physician in 1898, when his predecessor, General Leonard Wood, then a surgeon in the army, organized the Rough Riders.

An American Instructor in a Russian Dental School.—Dr. Oscar Gerber, a dentist formerly of East Orange, N. J., has been appointed Instructor of Prosthetic Dentistry in the Dental Clinic at St. Petersburg, Russia. Dr. Gerber is a graduate of the New York College of Dentistry and of the University of Pennsylvania, and after receiving his license from the New Jersey Board of Examiners went to Berlin. While there he received his appointment on the Faculty of the Russian College.

Dr. Mary Walker, the eccentric physician who dresses as a man, was nearly mobbed the other day in Syracuse, for some anti-imperialistic disparagement of President McKinley. A man who overheard her remarks, mistaking her for one of his own sex, was on the point of knocking her down when he discovered his error. After some threats and jeering by the crowd, she was allowed to go free.

Burning of an Insane Asylum.—The State Asylum for the Insane and adjacent buildings at Norfolk, Neb., were destroyed by fire on Monday of this week. Six hundred patients were in the institution at the time. Two patients are missing and it is supposed they were burned to death.

Obituary Notes.—Dr. Abram Litton of St. Louis died in that city on September 22 at the age of eighty-seven years. He was born in Dublin, Ireland, and came to this country with his parents when four years old. For half a century he held the chair of chemistry both at Washington University and the St. Louis Medical College.

Dr. William T. McKinley of Polk, Pa., died of apoplexy on September 14, at the age of forty-four years. He was a graduate of the Baltimore Medical College.

Dr. Lucius T. Sheffield, a dentist of this city, died on September 20. He was a graduate of the Harvard Dental College, and practised for a few years in Paris before settling in this city. His father was a widely known dentist in New London, Conn., where the deceased was born in 1854.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A ROYAL COMMISSION ON TUBERCULOSIS—SUGGESTION FOR ONE ON CANCER—SMALLPOX—WINTER HEALTH RESORTS—MAJOR ROSS—BROMPTON HOSPITAL—CHIGOE—RECENT DEATHS

LONDON, September 6, 1901.

THE Congress on Tuberculosis is not to be altogether fruitless. The King has issued a commission to inquire and report with respect to tuberculosis (1) whether the disease in animals and man is one and the same, (2) whether animals and man can be reciprocally infected with it; (3) under what conditions, if at all, the transmission of the disease from animals to man takes place, and what are the circumstances favorable or unfavorable to such transmission. The Commissioners nominated by His Majesty are Sir Michael Foster, Dr. Sims Woodhead, Dr. Sidney Martin, Professor McFadyean, and Professor Rupert Boyce. It must be admitted that these names are calculated to inspire confidence, and it is satisfactory to find England so prompt in setting about the inquiry so generally admitted to be called for. The commission will probably begin to take evidence early next month.

Apropos of tuberculosis, some publicity has been obtained here for views expressed by Professor Baumgarten in a Berlin journal. He refers to an experiment made by a physician, now dead, on patients with incurable cancer and sarcoma. They were inoculated with murrain bacilli—pure human bacilli being at that time unobtainable—without any effect, good or bad. Baumgarten says that at the post mortem of some of these patients, who were under observation to the end, he was present and found small scars at the point of injection entirely free from any trace of tubercle or bacilli. These experiments, therefore, were as negative as the converse ones practised by him, as well as Koch, with human tubercle bacilli on cattle. It is now admitted that cancer and sarcoma may coexist with tuberculosis in the same patient, even in the same organ, so that the old argument that persons with these tumors offer an unfavorable soil to the bacilli loses its force. But Koch's interpretation of the experiments is rejected by Professor Baumgarten, who regards the human and bovine bacillus as identical. The changes that take place in bacteria in different environments are, he thinks, sufficient explanation, as was pointed out by Lister and Nocard at the recent Congress. Though he thinks that cattle tuberculosis is comparatively innocuous to man, he admits that it may be transmitted, and so he does not venture to advise an interruption to the precautions that have been enforced to prevent the possibility of such transmission. This conclusion seems obvious enough; for the danger if Koch, after all, should not be right is too great to incur. This was recognized by Koch himself, who said in conversation after his paper was read, that he had stated the facts with which he had met, but if people thereupon threw over all precautions the responsibility would not be his.

Referring again to the commission, the question has been mooted, why not another for cancer? You will remember that the King in his address to the recent Congress referred to this terrible disease as having up to this time baffled the skill of the medical men of the world, and said the discoverer of a cure would deserve a statue in every capital. Knowing the suffering of a near relative of the King, we can understand the pathos of his prayer, "God grant that before long you may be able to find a cure for it or to check its course." Many doubt whether a Royal Commission would be the best way of promoting this end, but if the general public desires it, there is accumulated already plenty of material to employ one. The King would, no doubt, have a special pleasure in appointing one if his advisers thought it desirable. The medical world could have no objection, and would applaud the step. Even those who expected no available results would be glad to see the accumulated statistics marshaled by able men and their suggestions embodied in a report, such as a Royal Commission would probably make.

The smallpox outbreak has been met with energy and promptitude. A fall in the number of cases marked the close of the week. There were only three notifications on Saturday. On Sunday there were five admissions, on Monday nine, Tuesday six, Wednesday one. The outbreak has remained local, most of the cases occurring within a circle having a radius of a quarter of a mile. Five of the cases in the hospital ships were fatal on Saturday and Sunday, and seventy-six were under treatment on Tuesday, while several others were awaiting removal at the Shelter. On Wednesday the disease was reported to have broken out in the Workhouse Infirmary, Clare Market, from which a sick man had been sent a fortnight previously to another workhouse, where he died shortly afterward. His nurse and another inmate were subsequently attacked. Of course the other inmates were then isolated and disinfection attempted. But one naturally asks whether that nurse and inmate had been revaccinated. The Guardians have reported that the back of the outbreak is broken, and that all have been revaccinated who would accept it. In the case of a nurse, it may be said, that submission to the operation should be a condition of employment. It is stated that two patients have carried the infection from London. One of them was attacked at Mansfield; the other went to Maidstone and died there.

About his time of year winter health resorts begin to send forth assurances that their mortality is low, their sanitation satisfactory, and so forth. If whispers of epidemic diseases or rumors of bad drainage have occurred in the summer, it is proclaimed that the circumstances were met with promptitude, that in a very short time all danger disappeared and that now the health of the resort is phenomenally good.

Cannes is already sending its protest against the alleged slander current in the summer of a serious death rate from typhoid fever. The report, we are now told, was grossly exaggerated. It is admitted that there were some instances of typhoid, but that was as far back as May, and three or four cases do not make an epidemic. The deaths in May this year were only four above the number in the same month of the preceding year, and exactly the same as in May, 1899, namely fifty-two. These statistics are official, and it is asserted are ample refutation of the calumnious reports. It is insinuated that the Cannes outbreak may have been known elsewhere, but not in Cannes itself.

It may be remarked in connection with this matter that all along the Riviera—indeed from Toulon to Genoa, not to go farther—cases which English doctors would class as typhoid pass under euphemistic terms in the several localities. One favorite term of late years has been "grippe abdominale" and this is sometimes spoken of as a sequela of influenza. Health resorts are naturally reluctant to admit any danger to visitors, and those most in favor are generally ready to abate any nuisances complained of. But that any one is absolutely free from the possibility of typhoid is not to be admitted. In that respect I do not think there is much to choose between them.

Major Ronald Ross arrived from West Africa on Monday, and has expressed himself as having no doubts as to the success of the attempt to clear Freetown of mosquitos. He does not think the climate of the West Coast so deadly as often represented, but says that with care Europeans may live there as comfortably as in India. He is down for a paper on "Tropical Parasitology" next week at the meeting of the British Association for the Advancement of Science.

The Brompton Consumption Hospital is about to establish a country convalescent branch where the open-air cure can be persevered with. I hear that it will be fitted up for the reception of 100 patients. The site selected is near Bagshot. It might, perhaps, have been better at a distance farther from town.

Sir H. Colvill reports that the chigoe or jigger is spreading rapidly in Uganda, and he anticipates that this terrible insect pest will soon invade Arabia and even India. It is said that Emin Pasha's expedition carried the pest into new districts. South America is commonly considered the original habitat of the chigoe, but it seems to travel in all directions. Some friends of mine were greatly troubled by it when exploring along the Congo river, but fortunately for them they knew how to deal with it, and were able to teach the natives to extract it as soon as it lodged in the skin.

Brigade-Surgeon A. N. Hojel died on Sunday, aged sixty. He joined the Indian Medical Service in 1859 and retired in 1875. During his service he was employed at the time of the disturbances in Persia, 1866–1871, taking part in the dethronement of two revolutionary Sultans of Muscat, in the bombardment and capture of Bahrim Fort, and the capture and destruction of Arab war vessels and piratical craft. He was mentioned in despatches on these occasions. Afterward he became physician to Jamsetjee Jejeebhoy Hospital, and professor of physiology at the Grant Medical College.

Among other deaths last month are Dr. H. C. Buckley, J.P., died on the 26th ult., aged fifty-seven. He was a graduate of Aberdeen, and practised for some years in his native town, Llandilo, but having sufficient of this world's goods he retired in 1890 and came to reside in London. He was more than once asked to contest a seat for Parliament. Dr. Lawrence, professor of midwifery and gynecology at Bristol College, died on the 30th ult., while on his holiday in Devonshire. Dr. Cahill of Berwick-on-Tweed, who retired in 1896, having then reached his jubilee in practice, died on the 18th ult., from influ-

eaza. He was an earnest naturalist. Dr. H. W. Livett of Wells died on the eighty-seventh anniversary of his birth, August 21. Dr. Kelly of Glasgow, aged sixty-six, and Dr. J. H. Tuke (South Kensington, formerly of Stratton, Cornwall) both died suddenly, the former on the 18th, the latter on the 26th of August. Brigade-Surgeon Baker died on the 21st.

HYDROTHERAPY AND QUACKERY.

To the Editor of the Medical Record:

SIR: Two editorial articles in your issue of August 10 demonstrate that the MEDICAL RECORD is now, as it always has been, on the outpost of the great medical army, giving warning of danger or bringing good tidings of progress in the interest of suffering humanity.

To one who has for many years studied to enlist the interest of his colleagues in the clinical value of water, your able leader on "The Claims of Modern Hydrotherapy" affords gratifying encouragement, because it will doubtless arouse attention to the fact that "it is the duty of practitioners to become acquainted with the theory as well as the practice of hydrotherapy, to further the teaching of this branch of medical art in a thorough and practical manner in our medical schools, etc."

Your article on "Quackery in Germany" is also timely, for these "natural physicians" are already invading our country. Several of them thrive in New York City. Some of these prescribe boldly the water treatment; others pretend to practise it only under direction of physicians, while they really take every patient they can get, thus obtaining a clientèle from the medical as well as from the lay public.

In my little book on "The Uses of Water in Modern Medicine," I wrote (page 22): "It is a singular paradox that the German Government does not protect the people against these uneducated quacks. Whether they shall be allowed to pursue their calling here remains to be decided. Thus far, I know only one such hydrotherapeutic institute in New York, in which the treatment is most crude and unscientific, and under the management of an ordinary masseur. Let not the profession stand idly by, and again allow the value of water as a remedial means to be overshadowed by the efforts of these unskilled advocates." It is marvelous that this class of men has increased so enormously in Germany since the above was written, and it behooves us to take warning lest the clientèle of the educated physician, which already suffers from the inroads of Christian Scientists and other faddists, be still more seriously encroached upon by these self-constituted "water-curists." SIMON BARUCH, M.D.

ELBERON, N. J., September 15, 1901.

IODINE IN THE TREATMENT OF WOUNDS.

To the Editor of the Medical Record:

SIR: Permit me to thank Dr. Arthur Stern for his kind note published in the MEDICAL RECORD of August 24. In this note the doctor emphasizes my suggestion regarding the use of iodine in the treatment of wounds. Dr. Stern, however, errs slightly in assuming that Kocher and Tavel's book escaped my attention. Had it done so, I would be on record as the only surgeon who does not study everything that is new and good in surgery. I must say that modesty prevents including in this list my little manual on the theory and technique of surgical asepsis, which was published before Kocher and Tavel's book saw the light of day, and which, it is true, contains sentences similar to Kocher's, like "Necrotic tissues have to be removed with forceps and scissors." But I am afraid such suggestions are contained in other publications dealing with the same subject.

There is, however, another matter in this connection which doubtless escaped Dr. Stern's notice. A little closer examination of the subject shows that (1) Kocher and Tavel "advise either the frequent application of tincture of iodine or the packing of every small incision with a piece of gauze saturated in tincture of iodine, to be changed every three hours." With due deference to my eminent Swiss colleagues, this seems entirely too heroic a procedure. However, this is foreign to the present question. (2) A rereading of my little effort in the MEDICAL RECORD for August 3 does not convey to my mind anything else than what I intended to express, viz., the value of iodine tincture in the *primary* disinfection of wounds. My suggestion distinctly was to apply the tincture of iodine once over the carefully dried surfaces, and that further treatment be carried out on general principles. The difference in the two propositions seems to be evident.

I would be crassly ignorant of surgical literature if I did not know, and as I said in the article to which Dr. Stern refers, that the time-honored tincture of iodine was used for skin disinfection before. Indeed, those who used it for that purpose are so numerous that the mere mention of their names would occupy more space than my article and Dr. Stern's criticism thereof.

Although it is hardly worth while to discuss any questions of priority in this connection, thanks are certainly due to Dr. Stern for his kindly criticism which serves to emphasize so simple, albeit so valuable, a matter.

CARL BECK, M.D.

MOUNT PLEASANT, N. H., September 14, 1901.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 19, 1901.

Eosinophiles as Constituents of Pus.—Edward T. Williams further discusses the significance of the eosinophile blood cell, and concludes that it can no longer be regarded as a specific cell. It is a purely pathological product, resulting from a natural, alkaline decomposition of the body of a common leucocyte. It is, in other words, a necrotic cell.

The Home (Sanatorium) Versus the Climatic Treatment of Consumption.—Vincent Y. Bowditch says that (1) From his own experience in New England, he is strongly in favor of the erection of sanatoria for the treatment and cure of consumption wherever that disease prevails. (2) As to the relative results to be obtained by this method in favorable or unfavorable climates, he does not think we are in a position to judge fairly at present. (3) He believes that at present better results can in all probability be obtained by this form of treatment in the Western sections of our country, like Colorado, New Mexico, Southern California, and similar regions, than in the Eastern sections.

Movable Kidney, with Special Reference to Its Consequences and Its Etiology.—Francis S. Watson holds that movable kidney is by no means the harmless condition it has been said to be by many writers. He admits that movable kidney is often present in neurasthenic women, but believes that in such cases it is often the direct cause, and not merely an accompaniment, of the neurasthenia. And further, he says, movable kidney sometimes results in much more serious consequences than the production of neurasthenic symptoms. These are (1) hydro- and pyonephrosis; (2) fixation in an abnormal position of a previously movable kidney, and (3) in a few rare instances, gangrene of the organ produced by the occlusion of its blood vessels brought about by the rotation of the kidney upon its horizontal axis. He does not accept the list of causes (relaxation of the abdominal walls, sudden wasting of the perirenal fat tissue, increase in size and weight of the kidney, downward pressure by an enlarged liver, or a pleuritic effusion, or tight lacing) commonly given by writers on this subject, but says that the ptosis is due to the destruction of certain structures normally holding the organ in position. These are the structures which form the attachments between the posterior and upper aspect of the tunica propria, and the fascia covering the lumbar muscles, and the peritoneum covering the diaphragm, respectively, aided by the less essential ones connecting the anterior surface with the peritoneum overlying it.

New York Medical Journal, September 21, 1901.

Conjunctivitis from X-Rays; Incipient Retinitis Apparently Due to the Same Cause; Report of a Case.—The case is reported by J. W. Sherer. His patient was a physician aged twenty-nine years, who suffered from photophobia and eye-fatigue. Later conjunctivitis developed. The patient had been daily exposed to the action of the x-rays for three years and a half. The history of several similar cases is given. In a general way, Sherer believes that the changes in his cases were analogous to those resulting from prolonged and excessive exposure to solar light.

The Social Aspects of Dermatology.—In the second Lane lecture, Malcolm Morris speaks of local inoculable diseases, gives the history of the discovery of the itch mite, stating that the illustrious Napoleon was a sufferer from the malady, mentions the prevalence of pediculosis, and notes the great advance of the last century in ideas of personal cleanliness. He utters a note of warning against the excessive use of the flesh brush and other local applications, saying that over-scrubbing, especially with rough flesh brushes, in people with sensitive skins produces an irritable condition, and may even strip off the protective coating of the horny layer, leaving the denuded surface open to the invasion of microbes. It has been abundantly

shown that a varied flora of the latter kind flourishes constantly even on the cleanest skins. He also says that the common bedbug lies under some suspicion of being the carrier of tuberculosis to man, similarly, the flea may convey the plague, but the problem has not yet been completely worked out whether the flea gets the infection from the rat and conveys it to man, or whether it gives the infection to the rat, which in turn passes it on to man by poisoning his food with its tainted carcass or in some other way.

Medical News, September 21, 1901.

A Few Remarks on a Generally Unrecognized Ear Disease (Otitis Media Mucosa). Henry A. Alderton states that the recognition of the mucous type of exudative, non-perforative otitis media is often more difficult than that of the serous type. The mucous form occurs more frequently in adults. The affection follows a severe cold, grippal or otherwise. The symptoms are varied. There may or may not be pain. Often an intense tinnitus is present. There is a full feeling in the head. Cerebration is difficult. There may be dizziness. There is hardness of hearing. Inflammation of the nasopharyngeal cavities exists. There is generally very little change in pulse and temperature. There are certain systemic remedies which are beneficial, such as the iodide of potassium in increasing doses. But by far the best treatment is incision and evacuation of the tympanum, repeated if necessary, and always accompanied by regular politzerization and conscientious treatment of the nasopharyngeal condition.

Disappearing Tumors.—A. S. Warthin and W. A. Spitzley emphasize the following points: In spite of skilful clinical observation, the ultimate behavior of a tumor is seldom to be determined except by microscopical examination. Many neoplasms are taken to be malignant when really they are but the outcome of an inflammatory condition. Probably no true neoplasm, malignant in nature, ever disappeared except through retrograde changes induced in itself through infection of the tumor tissue, or through affections or infections of other parts of the body having, by reason of toxins, practically the same effect. To this there are extremely rare exceptions in which the disappearance of the growth takes place by an excess of retrograde processes over those of growth. We must look to the inflammatory process, acute or chronic, for the explanation of the appearance and disappearance of these masses of tissue which before, and even during, exploration appear to be actual new growths.

The Dilatation of the Cervix Uteri in Obstetric Practice.—Henry J. Garrigues first mentions certain drugs which are of more or less value in dilating the cervix. Atropine dissolved in sterilized water may be injected into the cervical tissue in the dose of $\frac{1}{4}$ grain. The application of a ten per cent. solution of cocaine may be used. Chloral hydrate, antipyrin, strychnine, quinine, and ipecacuanha have all proved useful in this respect. Various mechanical means are in use. Tamponade may be tried by inserting a strip of iodoform gauze into the cervical canal as high as possible, and then packing the vagina with gauze or cotton wrung out of one per cent. creolin solution. This is to be left till the next day. If circumstances demand a rapid dilatation, various methods are available—manual dilatation, dilatable bags filled with fluid, expanding metal dilators, and deep cervical incisions. Garrigues has found manual dilatation of great value. The bag of Champetier de Ribes is of great value for the induction of premature labor, and in cases of placenta prævia. Incising the cervix is indicated only when the cervix is obliterated and the os not sufficiently dilated. When the incisions are made, it is better to close them with sutures immediately after delivery.

Philadelphia Medical Journal, September 21, 1901.

Light and Radiance in the Treatment of Pulmonary Tuberculosis.—George G. Hopkins speaks of light as being a powerful germicide, the actinic rays being able to penetrate even deep-seated tissues. By means of Finsen's apparatus, the heat rays are eliminated. The writer has treated ten cases. Within a few days, cough, expectoration, high temperature, and nightsweats have been relieved. The appetite has improved rapidly. He expects much from this treatment in the future. The patient should not be exposed to cold for some hours after the treatment, as the pores are open, and the kidneys will suffer from sudden cooling of the skin. Careful examination of the urine in every case is most advisable.

Treatment of the Apparently Unaffected, or at Most but Slightly Involved, Eye in Cases of Glaucoma.—G. E. de Schweinitz advocates keeping the non-affected eye under the influence of a myotic until the other eye is entirely healed and free from irritation. He says that in cases of acute glaucoma the apparently unaffected eye should be operated upon as soon as the anterior chamber is restored in the opposite eye, i.e. as soon as the wound is closed, if indications show that it is likely to suffer a glaucomatous attack like its fellow, especially if the patient will probably pass from under observation. In chronic congestive glaucoma the same advice applies, and the operation should be urged if the apparently unaffected eye has had attacks of nebulous iridescent vision, associated with increased intraocular tension. In chronic simple glaucoma, if any increased intraocular tension whatever is shown, operation should be performed even with perfect central and peripheral vision. Even in this case there may be a scotoma. If so, operation should not be postponed. In absolute glaucoma, the rules laid down for cases of acute glaucoma are applicable.

American Medicine, September 21, 1901.

The Significance and Treatment of Floating Kidney in Women. Henry D. Beyea believes this to be a most important subject. The frequency of prolapsed kidney does not seem to be generally appreciated. The typical symptoms are nervousness, chronic indigestion, dragging pain in the loin, usually the right, abdominal distention, and often appendical or ovarian pain. He describes in detail the operation which he advocates. After the incision is made and the kidney is brought out through the wound, two pieces of ordinary rubber drainage tubing are passed around the kidney, one above and the other below the hilum. Neither the ureter nor vessels are interfered with. The kidney is replaced, the wound sutured and covered with an oblong piece of gauze, over which the tubes are gently tied. After three weeks the tubes are removed. In this time they have caused the formation of two connective tissue tubes, which permanently keep the kidney in a fixed position.

The Therapeutic Value of Alcohol.—Leon L. Solomon declares that alcohol should always be given tentatively, never as a routine medicine. It must be in a state of dilution before it can be absorbed. It is a conservator of vital power. Within certain limitations, it may be called a food. It adds force if it does not make tissue. Its employment in disease is manifold. The very young and the very old bear it better than those of other ages. It is useful in acute diseases, like typhoid, diphtheria, smallpox, septicæmia, etc. In malignant disease, alcohol gives comfort. In chronic suppuration and in wasting diseases, its effects are often surprising. In tuberculosis it improves appetite and digestion, and promotes formation of new tissue. It is always indicated when adynamia is a striking symptom. Muffled or absent first heart-sound is one of the first indications for its use in acute disease. Locally, it has various uses, for example, as a gargle, astringent, anæsthetic, and antiseptic. It is almost a perfect aseptic. It is locally, also, a hæmostatic, anhidrotic, and rubefacient.

The Lancet, September 14, 1901.

Note on a Case of Tetanus Successfully Treated by Antitetanic Serum.—E. M. Sympton's patient was a man of forty-five years whose nose had been cut by a fall on a rusty nail. The symptoms first appeared on the eleventh day. Bromide of potassium and chloral having been given without relief, the injection of serum was begun and continued at intervals for eight days with relief to the patient, who made a good recovery.

Intermittent Pulse under Chloroform.—The patient of R. R. Lakhdhir was a Hindu boy of twelve years, operated on for sinuses under the mastoid process. Examination previous to anæsthesia disclosed nothing abnormal. Whilst chloroform was being administered, he had struggled a great deal. When fully under its influence, his pulse was distinctly felt to beat according to a well-marked intermittent type, the cycle being that after every fourth beat there was a pause, followed by four beats and a pause, and so on. After the operation was over, and as the patient was coming from under the anæsthesia, his heart sounds and pulse were very carefully watched. The heart sounds were normal, and there was not the slightest trace of intermittency in the pulse. Since that time, the patient has been kept under observation, but he has never shown any sign of intermittent pulse.

Some Points in the Pathology of Pernicious Anæmia.—William Bain is disposed to agree with Hunter's assertion that there is under normal conditions a disintegration of red cells within the portal area. In pernicious anæmia this hæmolysis is increased, and the all-important question is the cause of the increased hæmolysis. Is it due to a toxin produced by a special microorganism, to an excess of some substance having a physiological origin, or to a new, and therefore essentially pathological, metabolic product? The area of its production appears to be within the portal system, for there is no hæmoglobin-

uria and therefore no free hæmoglobin in the general circulation. In brief, the facts are at present too scanty to justify a definition of the actual cause of the hæmolysis, yet sufficient to suggest the inadvisability of restricting attention to the discovery of a purely hypothetical microbic agent.

Changes Effected by Antityphoid Inoculation in the Bactericidal Power of the Blood; with Remarks on the Probable Significance of These Changes.—A. E. Wright lays down the following propositions. (1) The employment in primary inoculation of large doses of vaccine—meaning thereby doses sufficient to give rise to very severe constitutional symptoms—would appear to be always inadvisable, while it would probably be associated with danger in cases in which inoculation is resorted to in the actual presence of a typhoid epidemic. (2) The employment of moderate doses of vaccine—meaning thereby doses sufficient to give rise to marked but not unduly severe constitutional symptoms—would appear to be inadvisable when making primary inoculations in the actual presence of a typhoid epidemic. On the contrary, such doses would seem to be appropriately employed when an interval of several weeks is to elapse before exposure to infection, and when there are difficulties in the way of carrying out two successive inoculations. (3) The employment of small doses of vaccine—meaning thereby doses which produce only a slight constitutional disturbance—would appear to be the only appropriate form of inoculation in the actual presence of typhoid infection. It would seem to be also in all other cases the most appropriate form of inoculation. Such primary inoculation ought, however, in all cases to be followed up by second inoculations with an increased dose of vaccine. (4) When the blood of a patient who has recovered from typhoid fever is found to possess a bactericidal power inferior to the average, and when re-exposure to typhoid infection is contemplated, it would seem advisable to secure for the patient the additional protection associated with the possession of a high bactericidal power. (5) On the other hand, when the blood of a patient who has recovered from typhoid fever is found to possess a bactericidal power considerably above the average, it would appear to be impracticable to increase that bactericidal power by the inoculation of sterilized cultures. (6) Whenever a doubt as to the efficacy of a particular antityphoid vaccine arises—and such doubts may obviously arise, either in connection with modifications introduced in the methods of preparing the vaccine or in connection with prolonged storage of the vaccine under unfavorable circumstances—it will always be possible to arrive at a decision on the efficacy of the vaccine by observing the effect exerted by the vaccine in question upon the bactericidal power of the blood.

British Medical Journal, September 14, 1901

Caffeine in Carbolic Acid Intoxication.—G. A. Ferraby reports the case of a young man, aged twenty-three, who had taken crude carbolic acid, and was in a comatose state. All the means tried did not seem to lessen the coma, until a hypodermic was given of ½ gr. of caffeine dissolved in water with the aid of sodium salicylate. In about an hour the dose was repeated, and the patient recovered.

Case of Infection of Leprosy Through a Wound.—W. London Strain describes this case. The patient was a woman of fifty-four years, who had a breast tumor removed. Before the wound was healed, she returned to her home, where lived a son afflicted with leprosy, as was afterward learned. In about six months the woman returned to the hospital with a very acute infection of leprosy. The cicatrix gave evidence of the entrance of the bacillus lepræ at this point.

The Urine in Plague. Alice M. Corthorn, in her work on this subject, has gathered the following data. The specific gravity is usually fairly low. The quantity of albumin is a certain guide to the gravity of the prognosis. Albuminuria is very common in plague patients, but generally clears up with the other signs of acute disease. Casts, both hyaline and granular, are frequently present. Plague bacilli were not found in her cases. Traces of blood were found in a few cases. Retention occurred far more frequently in the fatal cases.

A Further Note on the Biological Test for Blood and its importance in Zoological Classification. George H. F. Nuttall is studying various kinds of blood, his object being gradually to produce various antiserums, and by means of them to study the reactions which occur with the blood of different groups of animals. The method of collecting is to soak up the blood (avoiding clots) on one end of a strip of pure filter paper about three by five inches. The animal may be dead or alive. The strips must not come in contact when still wet. The writer is desirous of obtaining as many specimens as possible. The classification and any notes may be written on the clean end of the strip.

The Influence of Color upon Anopheles.—George H. F. Nuttall discovers from experiments the colors in their order as preferred by anopheles. The result is as follows: Navy blue, dark red, brown, scarlet, black, slate gray, dark green, violet, leaf green, blue, pearl gray, pale green, light blue, ocher, white, orange, and yellow. Dark blue is most attractive. The khaki uniform should thus offer advantages. The writer believes this knowledge can be utilized in choosing tints for walls. He also suggests the use of traps of dark blue, for instance, in which the insects would congregate and could then be destroyed.

Inoculation and the Incubation Stage of Plague.—W. B. Bannerman states that in India those patients who were actually suffering from plague at the time of inoculation showed a case mortality of 48.8 per cent. only, which is not far from the death rate in the same outbreaks among those who developed plague more than ten days subsequent to inoculation. It is the general opinion of plague inoculators that it is advisable to operate on all who have been exposed to infection. The case mortality is not increased by inoculation, either in those who are in the incubation stage or in those in whom the symptoms of plague are already developed. No harm comes from the injection of Haffkine's plague vaccine, even in the presence of plague itself. There is little difference in the mortality of those attacked before and those after the first ten days' period after inoculation.

Berliner klinische Wochenschrift, September 2, 1901.

The Relationship of Human and Bovine Tuberculosis.—P. Baumgarten refers to some experiments carried out in 1893 under his supervision by Gaiser in which the difficulty of infecting cattle with human tubercle bacilli was shown, and then describes an instance in which the converse experiment, with, however, a different end in view, was carried out. The investigator, who has since died, impelled by the not unfavorable results that had followed the inoculation of various organisms such as that of erysipelas in cases of inoperable malignant disease, inoculated a number of such hopeless cases with tubercle bacilli. It happened that germs of human origin were not at hand so that organisms obtained from cattle and of cases so approved virulence were used. In half a dozen treated and subsequently examined post mortem by Baumgarten, beyond slight temporary local lesions absolutely no infection was produced. The question of just to what degree it is possible to influence the virulence and other characteristics of an organism by cultural changes is still in doubt and notwithstanding such evidence as the above, it is not right to assume a difference of species. While, the author believes that the actual danger of human infection through food products obtained from tuberculous animals is but slight, still it would be unwise in the extreme to give up any of the regulations at present in force until further investigation has brought more definite knowledge.

The Question of the Origin and Significance of the Basophile Granules and of Polychromatophilic Degeneration in the Red Cells.—G. Jawein was able to make some unusual observations in a case of bothriocephalus anæmia. The patient was a middle-aged man whose blood gave the usual characteristics of a progressive pernicious anæmia which continued to grow worse even after expulsion of the worm. Just as the patient was almost moribund, his red cells being reduced to one-half a million, signs of a slight catarrhal pneumonia developed, followed by almost instantaneous improvement. Three days later the number of erythrocytes had increased to 1,440,000 and the hæmoglobin had risen from eleven to twenty-six per cent., while numerous normo- and megaloblasts were found, together with all stages of basophilic granulation and polychromatophilia. In consequence the author concludes that the latter two conditions are really regenerative and not degenerative manifestations, as has heretofore been supposed, and his preparations show the various steps by which the origin of these appearances may be traced from the normoblasts by karyorrhexis. The presence of red cells containing basophile granules and of those showing polychromatophilia is therefore an indication of increased function of the bone marrow, and is to be observed in all cases of severe anæmia. It is easily possible that where the bone marrow has been only moderately stimulated, it may throw only half ripe, i. e. only granulated erythrocytes into the circulation, but not wholly unripe, i. e. nucleated cells.

Deutsche medicinische Wochenschrift, September 5, 1901.

The Rôle of Autointoxication in Epilepsy. Hebold and Bratz find that experiment on dogs and mice does not confirm the conclusions of those who believe that the

seizures of epileptics are due to autointoxication from bodies circulating in the blood, or at least excreted in the urine. Such substances were obtained from epileptics very shortly after attacks, and immediately injected into the animals, but with negative results. In an endeavor to produce conditions similar to those usually considered as predisposing to the disease, dogs were used for experiment that had previously been subjected to brain injury through a trephine opening, and in order to simulate hereditary taint, a bitch received alcohol in increasing amounts for eleven weeks before dropping her litter; but these animals also failed to react to the injection of the epileptic fluids.

The Disinfection of Cutting Instruments with Tincture of Green Soap.—J. H. Polok, carrying out Mikulicz's suggestion as to the antiseptic powers of the tincture of green soap, was led to try its value in sterilizing instruments. The results of his experiments lead him to conclude that for all instruments that will stand ebullition in soda solution is the best and safest method of disinfection, but inasmuch as the alcoholic solution of green soap kills staphylococci in fifteen minutes, this method is available for knives, etc. Alcohol, in a strength of fifty per cent., is a more energetic disinfectant than in greater or less concentration, but is less efficient than the tincture of soap. The method that for over half a year has been successfully used in Professor Straub's clinic consists in placing the instruments after use in the soap solution for fifteen minutes, after which they are carefully cleaned. Before operation, they are again put into the liquid for the same length of time, are wiped off with sterile gauze and placed in fifty per cent. alcohol, or three per cent. boric-acid solution. The method is especially adapted for use when, as in office or country practice, boiling cannot be carried out, and it gives reliable results.

Observation on the Relationship between Alterations of the Freezing Point of the Blood and Nervous Disturbances.—A. Bickel says that, in spite of the older belief to the contrary, sodium chloride possesses properties which are distinctly toxic to living matter, and specifically to the nervous system. These nervous manifestations, which are due to the chemical constitution of the salt, are, however, usually relegated to the background by other "general" effects produced as the result of its physical properties. The intravenous injection of salt solution in rabbits first causes a gradual drop in blood pressure, which, shortly before death, is replaced by a rapid rise. Cardiac arrhythmia sets in early, while the respiration remains unchanged for some time, then becomes accelerated and finally slowed. In addition, marked diuresis occurs, but the most notable symptoms are those due to irritation and inhibition of the nervous system. Reflex excitability is exaggerated, going on to tonic and clonic convulsions with tremor, nystagmus, and ultimately coma and death. In studying these phenomena in rabbits, after injecting varying quantities of twenty per cent. salt solution, the author found that the nature of the effect produced depended largely on the rapidity of injection of the solution. In endeavoring to reproduce the conditions existing in renal insufficiency, the solution should be injected just as slowly as is technically possible, and the freezing point of the blood must reach a lower point than is usually found in animals in whom the uræmic symptoms have been brought about by interference with the kidneys. The manifestations of increased nervous irritability observed in uræmia are not directly dependent on the increase of molecular concentration of the body fluids.

French Journals.

Cystic Tumor of the Skin.—Cornil reports this case. Under the microscope it resembled a myxoma. It was a sebaceous cyst of long standing, modified by chronic inflammation consecutive to surgical intervention. It exemplifies the difficulties sometimes met in the diagnosis of tumors, as to whether they are malignant or benign, the various parts presenting different aspects.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, September 5, 1901.

Melanotic Carcinoma, Stomach and Large Intestine Being Impregnated with Pigment.—F. X. Gouraud and de Lacombe present this case. The tumor, about the size of an egg, was taken from the little toe of a man seventy-six years old, who had died in a state of advanced cachexia. Histologically, the tumor was a carcinoma. The pigment gave neither the reaction for iron nor that for melanin, but seemed midway between the latter and hemosiderin. The tumor had been growing for ten months, and there seemed no generalization with the exception of enlarged inguino-lumbar ganglia and one cutaneous nodule. But the circulating pigment had impregnated the stomach and large intestine, leaving the small intestine intact. The former two organs were as black as if injected with nitrate of silver.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, September 5, 1901.

Toxicity of Phosphorus. According to M. J. Cau, the toxicity of phosphorus varies according to the conditions present. It is probable that children support this medication badly. The existence of certain lesions, such as myocarditis, cirrhosis, and nephritis, should be considered as absolute contraindications to the use of this drug. It is dangerous to prescribe phosphorus for a long time if the kidneys are not in perfect working order. Individual susceptibility also plays an important rôle in the toxicity of phosphorus.—*Gazette Hebdomadaire*, September 12, 1901.

Indications for Phototherapy in the Treatment of Lupus and of the Limited Dermatoses of the Face. Leredde advocates phototherapy in the treatment of tuberculous lupus, though the indications for this treatment in lupus erythematosus are less frequent. Great patience is necessary in the use of this method, as after apparent cures there are sometimes recurrences. The treatment as applied to vascular nævi has met with considerable success. Excellent results have also been obtained in acne rosacea. The results also in cases of sycosis have been very encouraging.—*La Presse Médicale*, September 7, 1901.

American Journal of the Medical Sciences, September, 1901.

A Contribution to the Pathological Anatomy of Sporadic Cretinism.—Frederick A. Packard and Alfred Hand, Jr. report their observations of a sporadic cretin. The boy was admitted to the hospital at the age of six years. Rapid improvement followed the administration of thyroid extract. About a year after his first admission he contracted typhoid fever. He showed practically no power of resistance, and died from asthenia one week after the onset of his illness. Autopsy showed the following points: The pituitary body was enlarged, besides which nothing important was noted in the brain. The thymus gland was greatly enlarged. There was great deficiency in the colloid substance of the thyroid gland and calcification of the walls of the arteries going into it. The lesions throughout the organs produced by the typhoid toxin were intense, there being in the liver a universal fatty degeneration of the parenchyma.

Pseudomembranous Inflammation of the Mucous Membranes Caused by the Pneumococcus.—Charles Cary and Irving Phillips Lyon describe this attack which occurred in the course of an acute lobar pneumonia in a boy of eleven years. They give the following summary: Acute lobar pneumonia of both bases, with development during the first ten days of a profuse pseudomembranous exudate, first upon the tonsils and quickly extending to the mucous membranes of the lips, tongue, cheeks, palate, throat, and nose, and transferred to the eyes, glans penis, and anus; physical signs of fibrinous pleuritis, marked and persistent tympanites; membranous shreds and mucus in the stools. Microscopical examination showed an absence of the bacillus diphtheriæ, streptococcus, saccharomyces albicans, etc. The diplococcus pneumoniæ was present in abundance in the sputum and in the exudate from all locations. Diagnosis pneumococcic infection resulting in acute pneumonia, pleurisy, and fibrinous exudation upon the mucous membranes.

Hydatid Disease of the Breast.—Robert G. Le Conte characterizes this tumor as a small, hard, painless mass which may be in any part of the glandular breast tissue. It moves freely with the surrounding tissue. Its growth is slow. It occurs only in women in the period between puberty and the climacteric. It is generally smooth and round or oval in shape. It remains firm until it is quite large, and rarely then presents the characteristics of a cyst. Inflammation outside the sac is attended by swollen axillary glands, severe pain, irregular outline, and adhesion to the skin. This condition, or degeneration of the sac wall, is followed by death of the causal organism and a spontaneous cure through ulceration or encapsulation. Only by the use of the exploring needle and the microscope can the diagnosis be positively made. The treatment should always be operative. As to the mode of entrance of the parasite, the eggs probably enter the stomach, where their envelope is digested by the gastric juice and the enclosed embryo set free.

Granular Degeneration of the Erythrocyte.—C. Y. White and William Pepper conclude that "The granules are a constant finding in cases of lead-poisoning, and appear very early in patients under the influence of lead salts, long before subjective or other objective symptoms can be demonstrated. The granules disappear in cases [illegible]

lead-poisoning [illegible] adolescence [illegible] established. Apparently lead does not produce an immunity, as one of the patients worked for twenty-four years, another for twenty years, without having pronounced symptoms of lead-poisoning, and in both of these cases the granules were present in moderate numbers. The granules may be produced experimentally in dogs, appearing in a very few days after the beginning of the experiment, and increasing as the intoxication becomes severe. The granules in the experimental cases are rather fine, and show a tendency to clump at first; later all varieties appear. The writers believe that these granules are the result of a true degeneration of the erythrocyte, and have no relation to unclean fragmentation or to polychromatophilia.

Report of an Interesting Case of Aneurysm of the Internal Carotid Artery.—Walter B. Johnson reports a case of dissecting aneurysm of the internal carotid artery. The patient was a boy aged four years. The child had suffered for more than a year with an acute suppurative otitis, the left ear discharging pus during that time. The present trouble was ushered in by the development of an acute inflammation of the throat. This was followed in ten days by a swelling in the left tonsillar region. An attendant tried to rupture the tumor with the fingernail. Within a few hours there was a very considerable hemorrhage from the left ear. On the next day, when during examination of the child the tongue was forcibly depressed, there was a second profuse hemorrhage from the left ear. The tumor mass did not pulsate at any point, was not easily compressible, and over it no aneurysmal bruit was to be heard. Examination of the tonsillar mass which was excised showed no evidence of carcinoma or of tuberculosis. Tracheotomy was performed. For a month there was steady improvement, when an attack of bronchitis occurred. About three weeks later the child suffered from severe hemorrhages from the nose and mouth, and died from exhaustion within three days.

Therapeutic Monthly, August, 1901.

Scurvy in the Mountains of Colorado.—G. H. Cattermole describes this case of a miner fifty years old who for seven years had lived at an altitude of about 8,000 feet, during which time he had prepared his own food, which consisted largely of bread, salt meats, and canned goods. On his entrance to the hospital he presented a general cyanotic appearance of the skin and mucous membranes. The gums were swollen, spongy, and blue, and bled freely. The tongue was swollen and speech thick. The breath was offensive. On the shins were several dark-blue spots. There were marked swelling and œdema of the arms. When the diagnosis of scurvy was made he was started on a generous meat and vegetable diet, with fresh fruit at meal times and lemon juice between meals; aromatic spirit of ammonia was the only medicinal agent continued. The cyanosis and edema disappeared, the mucous membranes became more normal, and his mental status was much improved.

Report of Two Cases of Epithelial Cancer Treated by Means of Chemical Caustics.—Jay F. Schamberg reports these cases. The first patient was a woman of eighty-three. The ulcer was on the right cheek. At first a twenty-five per cent. pyrogallic acid ointment was applied for a week. After this a fifty per cent. of caustic potash solution was painted over the part every three or four days for about ten days. Then the stick of caustic potash was applied to the deeper tissues after cocainization. Finally there was employed for thirty-six hours an application of arsenous acid twenty-five per cent. in powdered acacia with sufficient twenty per cent. solution of cocain to make a paste. While the parts were granulating, a simple carbolized petrolatum was used to prevent crusting. At the end of four weeks the ulceration had completely healed. The second patient was a man aged forty-seven years. The ulcer was on the upper lip and right ala of the nose. The patient had been operated on a year ago, but the growth had returned. A fifty per cent. arsenous acid paste was used on the epithelomatous tissue while a stick of caustic potash was used in the subcutaneous tissue. There is now present only a healthy granulating ulcer. The writer believes that the use of chemical caustics should have a distinct place in the treatment of cutaneous cancers, although in extensive, deep-seated carcinomata he believes in the use of the knife.

Annals of Surgery, September, 1901.

Frequency of Recurrence of Sarcoma with Especial Reference to Amputation at the Hip Joint on Account of this Neoplasm.—J. A. Wyeth says that from statistics collected by him he finds that of 207 cases of amputation at the hip by the Wyeth method, 131 were done for sarcoma. Of this number fourteen or ten and six-tenths per cent. ended fatally, wholly or in part as a result of operation. Of the 117 cases surviving operation, he has histories of eighty-three. In fifty-two of these it is noted that the disease recurred, but since, in one instance, the neoplasm could not be entirely removed, this case is properly excluded. There are then a total of fifty-one, or over sixty-three per cent., ending fatally by recurrence. He believes, however, that this estimate of ratio of recurrence is too low. Reference is made to the cases of other surgeons and several personal experiences are related.

Studies of the Blood in Its Relation to Surgical Diagnosis.—Richard C. Cabot, John B. Blake, and J. C. Hubbard conclude as follows: (1) At the end of complete anæsthesia there is occasionally a slight increase of leucocytes, but seldom a marked leucocytosis. (2) At the end of operation, there is a considerable leucocytosis in one-half the cases, and in almost all cases some increase beyond that found at the end of complete anæsthesia. (3) Simple uncomplicated fractures seldom increase the leucocyte count to any considerable extent. (4) The blood after operation for malignant growths is not necessarily much impoverished, and regenerates, in favorable cases, quite normally. (5) A variation in the hourly leucocyte count exists in other conditions than the preperforative stage of typhoid fever, and may occur in health. (6) Very violent physical exertion produces in the blood a condition which leaves physiological limits, and approaches or is identical with that found in disease.

The Blood Changes Induced by the Administration of Ether as an Anæsthetic.—J. C. Da Costa and F. J. Kalteyer draw the following conclusions: (1) The number of red corpuscles is influenced by many factors associated with and accompanying the anæsthetic state. The character of this change is, as a rule, a polycythæmia; rarely, an oligocythæmia. (2) The nature of this polycythæmia seems best explained by a lessening of the watery elements of the plasma, thereby reducing the total volume of the liquor sanguinis, and consequently causing concentration of the blood. (3) The three important factors incident to the polycythæmia are: (*a*) The period of preparatory operative treatment; (*b*) the anæsthetic state; and (*c*) the postoperative stage. (4) The blood inspissation is, as a rule, most pronounced immediately after the termination of the anæsthetic stage. (5) The hæmoglobin is always reduced absolutely; in some instances there is an apparent increase, but this rise in the percentage of hæmoglobin is never parallel with the rise in the number of red blood cells. The individual corpuscular hæmoglobin value is therefore reduced. (6) The duration of the anæsthetic state and the amount of ether may influence the blood changes; but the extent of the disturbances could not be determined on account of the many modifying factors. (7) The amount of hemorrhage does not seem to affect the composition of the blood. (8) On account of the hæmolysis, which is shown by the fall in corpuscular hæmoglobin after operation, a very low percentage of hæmoglobin must be regarded as a contraindication to the administration of a general anæsthetic. Below fifty per cent. is a dangerous level.

The Journal of Tropical Medicine, August 1, 1901.

Remarks on Yaws and on the Diseases Most Frequently Met with in St. Lucia.—St. George Gray reports cases of yaws, in which the chief points to be noted are *sessile* granulomata, which under favorable conditions dry up, leaving macule which disappear; and *femoral buboes*, which are nearly always present in every case of yaws that has ceased to be local. Granulomata that are exposed to the air dry more rapidly than those kept moist by perspiration under the clothing. As to diseases met with in St. Lucia, West Indies, there have recently been epidemics of measles and whooping-cough; typhoid fever is practically unknown; pneumonia, phthisis, and bronchitis are common, and also influenza does not pass St. Lucia by.

Lecture on Plague.—W. J. Simpson, in speaking of the plague epidemic in Cape Town, says that treatment by inoculation is perfectly harmless if properly performed with properly tested vaccine, and the immunity secured is an exceedingly high one. Unfortunately, the inoculations do not give immediate protection, six or seven days being required to secure immunity. Of the inoculated the equal of .875 per 1,000 have been attacked; of the uninoculated, 4.75 per 1,000. The author believes that in a country such as South Africa, with its native and mixed population, a large proportion of which is living under the gravest unsanitary conditions, and cannot in a few months be taught to be clean, inoculation of the unsanitary classes and of those living in infected areas is the only practical and effectual safeguard against plague.

The Etiology and Treatment of Prickly Heat.—A government medical officer of the West Indies believes

prickly heat to be a true eczema, and that its presence is protective when established. It is nature expressing You have been trying to introduce into the system poisons that I have thrown out once, I won't have them, so I throw them out again." The author avoids soap, and uses almond oil and lanoline, one to seven, with oleum rosæ. To this he adds dusting powder. His chief reliance, however, is on thin cotton garments under his Jaegers, and changing his clothes three or four times a day. The cotton garments can be washed in a hand basin, with ammonia and water, and dried quickly; the Jaegers can be worn a week, free from all trace of perspiration or odor. Under this regime prickly heat quickly disappears

Bulletin of the Johns Hopkins Hospital, August.

An Historical Note upon Diptera as Carriers of Diseases.—Howard A. Kelly reviews the account given by Paré of the great destruction wrought by flies on the battlefield after the battle of St. Quentin 1557. He also quotes from Déclat, 1805, and declares that all that is lacking to prove the absolute correctness of this writer's observations is vigorous scientific experiment. Déclat writes: (*a*) The fly visits bodies in process of decomposition. (*b*) Decomposition is nothing more or less than destruction by ferments which are living microscopic structures. (*c*) The fly transports on its feet, its wings, its proboscis, or its mandibles some of these destructive agents, and this material is carried to and deposited upon the living body, where, if there is any abrasion or fissures or any solution of continuity whatever, the contagious virus does its work by entering the vascular system and multiplying indefinitely

Abstract; The Frequency of Gallstones in the United States.—C. D. Mosher concludes from the statistics consulted that gallstones are less frequent in the United States than in Germany, the proportion being 6.94 per cent. to 12 per cent. The frequency of gallstones in a given number of cases will increase with the age of the patients examined. The American cases tend to confirm the statements of previous observers that gallstones are rare before the thirtieth year and more frequent after that age. Gallstones are more frequent in the white than in the black race, the American cases showing a frequency of 7.85 per cent. in the whites and 5.51 per cent. in the negro. Women are more liable to have gallstones than are men, the American cases showing the frequency in 618 women to be 9.37 per cent., and in 1,037 men to be 5.94 per cent. The American women have gallstones only about half as frequently as the German women. In the United States only about one woman in every ten has biliary calculi, while in Germany, according to Naunyn, gallstones are found in 20.6 per cent., or about in one woman in every five.

Tendon Transplantation.—Sydney M. Cone believes that before operation is decided upon, the patient should have every possible chance for the relief of the deformity. Massage, electricity, and active and passive movements are usually recommended for one or two years before operative measures are advised. If immobility prevents the limb being placed in a good position, "redressement" must precede the operation. A thorough electrical and physical examination must be made. Incision will disclose the condition of the muscle, the normal being dark red, the paretic, rose red, while the completely paralyzed muscle is yellow. The method of joining the tendon varies, but the least possible traumatism to sheath and tendon is required. It is desirable to have the broadest union possible and a freshly serrated surface. Silk is generally preferred, and the quilted suture is desirable. The first dressing is done in nine days, but the limb must remain in plaster for about five weeks, after which massage and passive motion are indicated. In musculospiral paralysis, one or more of the extensor tendons are usually shortened, while at the same time a flexor muscle is transplanted. The flexor generally used is the flexor carpi ulnaris. Some surgeons carry it between the radius and ulna, while others wind it around the wris

Archives of Pediatrics, September.

Probable Etiology of Rectal Polypi in Children.—Francis Huber has observed one common feature in all of his cases—rectal polypi were found only in patients who at the same time showed evidences of lymphoid hypertrophies in the nasopharynx with other manifestations of the constitutio lymphaticus, status lymphaticus. Besides the nasopharyngeal changes, the abdominal lymphnodes are much enlarged. In all cases examined by the writer, Waldeyer's tonsillar ring was involved. As far as the large intestine is concerned, the pathology is identical in status lymphaticus and in the case of the polypi

Lamellar Desquamation in an Epidemic of German Measles or of "Fourth Disease."—Frederick T. Simpson reports this epidemic. There was uncertainty at first as to the diagnosis—whether it was German measles or mild scarlet fever. The writer believes that there were two forms of disease, rubella and "fourth disease," so called by Dr. Duke. Here was a series of cases of an eruptive fever following an incubation period of at least two weeks; eight of the patients desquamated in strips, five of them had had scarlet fever, and four and possibly seven had had German measles. A number of patients also had a second rash, which appeared between two and three weeks after the first. It lasted several days, and though there was a slight rise of temperature, there was no feeling of malaise. The patient appeared to be having a second attack of the disease. The rash was coarse and discrete. The combination of symptoms noted above certainly indicates the probability of the existence of an eruptive fever differing from those already known.

Pernicious Anæmia in Infants, with a Preliminary Report of a Case.—T. M. Rotch and Maynard Ladd declare that cases of primary pernicious anæmia in childhood are rare. As far as can be inferred from the comparatively few autopsies, the pathological changes in this disease as observed in infants do not differ essentially from those in adults. Emaciation is rare, but there is extreme pallor of all the body tissues. Hemorrhages in the various organs are often found. The bone marrow offers the most typical lesion, being red and having many characteristics of the embryonic type. In it are many nucleated red blood corpuscles. The liver, kidneys, pancreas, and heart, generally show marked fatty degeneration. There is generally glandular atrophy of stomach and intestines. The spleen is not as a rule much altered. Freshly drawn blood does not coagulate readily, nor does it form in rouleaux. There is a reduction of its bulk and specific gravity. The hæmoglobin is much diminished, but the relative amount in the individual cells is increased. There are often large numbers of oval and pyriform cells. As to treatment, feeding is of chief importance. Iron may be of benefit. Arsenic is not always tolerated.

The Edinburgh Medical Journal, September.

Typhoid Bacilluria.—C. J. Lewis says that the importance of this complication of enteric fever has only recently been accorded its full significance. Its essential feature is the presence of the *Bacillus typhosus* in the urine, either alone or associated with other organisms. There may be no symptoms to call attention to this condition, especially during convalescence, a fact which the physician should bear in mind. It does not usually appear before the third week, and may continue for a varying length of time. From five to one hundred and seventy millions of the bacilli are found per cubic centimeter. Proof that the bacillus is excreted in the urine, in a condition capable of infecting other persons, is not wanting. To prevent the spread of enteric fever by means of the urine, efficient disinfection should be practised. By far the best is boiling the urine, but where this is not practicable, equal quantities of 1:20 carbolic acid and urine should be mixed, allowed to stand an hour, and then discharged into the drains; or perchloride of mercury in quantity to give 1:1,000 strength when added to the urine.

Tuberculosis of the Heart Muscle.—Raymond Crawfurd says that the frequency of adherent pericardium in this affection would suggest that the usual mode of propagation to the heart muscle is by direct extension. A second mode of access is certainly through carriage by the blood, while Cabannes and others have brought forward strong evidence of a third mode of propagation by the lymph stream. Tuberculosis of the heart muscle occurs in one of three typical forms: the *large tubercle*, from the size of a lentil to that of a hen's egg; the *miliary tubercle*, and true *tuberculous myocarditis*, in which the heart muscle is invaded by areas of fibrous tissue in which are found collections of young cells and giant cells with Koch's bacilli. The main changes in the heart muscle are of degenerative type, tending more or less to atrophy from pressure; sometimes, however, a localized fibrosis is seen, while the more distant muscle undergoes hypertrophy or dilatation. The study of the clinical aspect of myocardial tuberculosis is most unprofitable. Diagnosis is impossible, and for the most part the condition is masked by the manifest evidence of tuberculosis in other organs.

Treatment of the Ataxia of Tabes by Means of Co-ordinated Exercises.—Edwin Bramwell says that many cases of tabetic ataxia are greatly benefited by this treatment, but that it may be contra-indicated where

there are such complications as grave cardiac disease, serious bladder trouble, a disorganized joint, a perforating ulcer of the sole of the foot, etc., or in the case of an acutely developed ataxia. The best results are obtained in persons who take an intelligent interest in the exercises and are gifted with mental concentration and perseverance, also in those who have been adepts in such exercises as bicycling, skating, etc. The patient must be made to understand that it is not the muscular force which he uses in performing the exercises which is of importance, but the care and precision with which he makes the individual movements. The writer had recently the opportunity of treating a man who had been unable to walk or stand for three years, and who, after ten weeks' treatment, was able to walk alone with the aid of a stick. Directions are given for exercises to be taken in bed, standing, and walking. Patience and perseverance on the part both of the patient and the physician are required if full benefit is to be received from this treatment.

Revue de Chirurgie, August 10, 1901.

The Radiograph in Pulmonary Surgery.—Th. Turner considers the radiograph a distinct aid in the diagnosis of pulmonary lesions. When it confirms the results obtained by auscultation and percussion, we need make no further inquiry. Should the results not agree with the plessimetric signs, then our attention should be directed to the locality indicated by the radiograph. If it gives negative results, especially when the lesion is on the left side, our diagnosis will have to be based on percussion and auscultation. x-rays may fail in the case of hydatid cysts, as they cannot indicate the multiplicity of foci which are contiguous or near each other.

The Pathogenesis of Ranula.—L. Imbert and É. Jeanbrau describe the cysts with ciliated epithelium which are situated on the floor of the mouth and called ranula. The ordinary form is not characterized by its pathogenesis, which is as yet undetermined, nor by its symptomatology nor etiology, but by its histological structure. The various theories in regard to the formation of ranula, such as degeneration of the sublingual glands and salivary retention, seem unsatisfactory to the authors, who have been led to believe in a congenital origin, some defect in development as yet not understood, but perhaps connected with the history of the branchial.

The Pathogenesis of Flat-Foot.—De Vlaccos has found by a study of numerous skeletons that a perpendicular line drawn through the middle of the articulation of the foot rarely traverses the middle of the astragalus, while the calcaneum is altogether outside of it. It is easy to see that perpendicular pressure acting chiefly upon the internal portion of the bones of the foot would tend to produce flattening of the plantar arch followed by external rotation. In a normal condition the physiological tendency to deviation is counteracted by the strong tendons of the tibia and by the flexors. Under certain conditions, however, which weaken the action of these muscles, the calcaneum yields to the pressure, and turning around the horizontal anteroposterior axis inclines to one side, and drags the astragalus with it. Ill-fitting shoes are merely a contributory cause, since flat-foot is found among people in the East who have never been shod.

Revue de Médecine, August 10, 1901.

Adiposis Dolorosa.—Charles Féré says that the more or less disseminated but irregular deposit of fat beneath the skin, coinciding with pain, in the absence of all other conditions which might produce the pain, has been considered by Dercum to constitute a morbid entity which he calls adiposis dolorosa. In this form of dystrophy the fat usually forms in symmetrical masses on trunk and limbs. The author holds that we cannot in all cases connect the adiposity with thyroid dystrophy, although in some cases such an origin may be suspected. Neither do the pain and the obesity always coincide, so that, on the whole, it is fair to conclude that Dercum's syndrome is an accidental one, the pain being a mere nervous incident in an obese patient.

A Case of Peripheral Neuritis of Malarial Origin.—M. Busquet reports the case of a man of twenty-four years, suffering from inability to walk and supposed paralysis of both forearms and hands. The triceps and the supinators and extensors of the forearm were notably atrophied in the right arm, but slightly affected in the left. There was hyperæsthesia of the hand, and diminished sensibility existed in the arm and forearm on both sides. The lower limbs were immobilized by pain, but there was scarcely any atrophy. Lead poisoning, syphilis, and alcoholism could be excluded in the etiology. But as the peripheral paralysis had come on at the close of an attack of pernicious malaria, a diagnosis of malarial neuritis was made and borne out by the results of treatment consisting of quinine, strychnine, and arsenic. The patient is at present practically cured.

The "Neurosis of Anguish."—P. Hartenberg says that this neurosis described by Freud of Vienna in 1895 as a morbid type distinct from neurasthenia, is characterized by general nervous hyperexcitement, a chronic condition of anguish or "anxious expectation," acute attacks of anguish with dyspnœa, palpitation, sweating, etc., rudimentary crises with various cardiac, pulmonary, and digestive disturbances, phobias, and obsessions. The "anguish" is the chief symptom, and consists in the constant and agonizing expectation of death, or of misfortune in some form or another, the imagination adding up every possible accident and illness. Freud believes the condition to be of sexual origin, due to non-satisfied desire. The author, however, does not believe this to be the only cause, but maintains that all exhaustion or overwork of the nervous system may induce the condition. Neurosis of anguish should be differentiated from neurasthenia. Treatment consists in hygiene, rest, isolation, hydrotherapy, electrotherapy, opium, etc.

Archives de Neurologie, August, 1901.

A Case of Persistent Amnesia Following an Attempt at Suicide by Means of Carbon Dioxide.—M. Truelle and M. Petit report a case in which the amnesia sometimes following carbonic-acid gas poisoning was protracted to an unusual length of time, the patient, ten months after the attempt, having almost complete loss of memory. The cause of the persistence of the amnesia after all the other symptoms had disappeared was somewhat obscure, hysteria, mental shock, and alcoholism having to be excluded in this case.

Statistics Relating to the Service of "Gynecological Observations" of the Public Insane Asylum of Ville-Evrard in 1899.—Lucien Picqué and M. Febvré examined sixty-six of the women patients in that institution, and found genital lesions in fifty-nine. Considering the fact that it is generally conceded that pelvic disorders have a decided rôle in the production of insanity, these authors think it deplorable that French law should allow asylum physicians to make gynecological examinations only when consent of the patient's relatives is obtained. In this particular asylum, consent was given for only sixty-six out of about 450 patients. A mentally deranged person may be torn from her family and deprived of liberty and the use of her property, but it is illegal to care for her health in the way most likely to restore it and her reason! The situation is thoroughly illogical.

Russki Arkhiv Patologii, etc., N.s. 5 and 6, 1901.

Enteritis Due to Amœbæ in St. Petersburg.—W. Kernig and A. Ouké report a case of acute gastroenteritis accompanied by hyperpyrexia, the symptoms observed being due to a primary invasion of the digestive tract by amœbæ. The authors review the history of cases of dysentery and enteritis traceable to the same cause, including some observed in St. Petersburg. Experiments on the amœbæ coli are described.

The Rôle of the Immunizing Substances in Phagocytosis.—J. Sawtschenko, having conducted a number of experiments, asserts that immunizing serum may cause the phenomenon of phagocytosis in two ways: first, by fixing itself upon the object of the phagocytosis, *i. e.* the red blood cells or the microbes, second, by entering into the composition of the protoplasm of the leucocytes. Thanks to this double affinity, it causes the avidity between the leucocyte and the object of the phagocytosis. The first step in the process consists of the phagocytosis of the red blood cells in the liver and spleen, followed by the solution of these cells in the plasma, due to the appearance of the alexins which result from the destruction of the leucocytes.

Direct Amitotic Division of the Red Blood Cells in Cold Blooded Animals.—A. Silberberg says that the hypodermic or intramuscular injection of anthrax cultures in a frog induces a marked proliferation of red blood cells. The special point to be noted is that this proliferation occurs not only by karyomycosis, but also by amitotic division, this has never been observed before.

The Maculated Red Blood Cells in Malaria.—W. Stephansky says that in staining malarial blood by the Ruge-Romanowsky method, he found that in all tertian cases the parasite-infected red corpuscles, while not stained, show a number of red spots on their surface. These spots are always red, always of equal size, and uniformly distributed within the cell, and increase in size with the age of the parasite. It is possible that, like certain other special appearances, these spots may be due to the disintegration of the chromation which occurs within the red blood cell.

Nissl's Corpuscles in the Nerve Cells.—M. Polowzow-

vinoff states that his researches have led him to an opposite belief from that held by Keld, who claims that the corpuscles of Nissl are not a morphological part of the nerve protoplasm, but a precipitate of some substance as yet unknown. Fresh nerve cells stained by toluidin show the Nissl corpuscles very clearly, for about ten or fifteen minutes only. The rapid discoloration is evidently due to the reducing action characteristic of living protoplasm. The decolorized cells have precisely the same appearance as non-stained cells, and in neither one are Nissl's corpuscles to be seen, so that the coloring matter has evidently no effect on living protoplasm. The author concludes that Nissl's corpuscles form an organized portion of living protoplasm.

Monatsschrift fur Geburtshulfe und Gynakologie, July, 1901.

Birth Palsies.—L. Stolper says that paralyses in the domain of the bronchial plexus due to the use of forceps occur only when the head is in the extended (deflected) position, and either the rules governing the application of the instrument have been neglected or the extension has not been recognized. Palsies through clavicular pressure are possible when the arm and with it the clavicle have been forcibly pressed upward and backward. In head presentations strong traction during the birth of the shoulders may cause paralysis through the strain on the fifth and sixth cervical nerves when the head is inclined laterally, the injury resulting on the side opposite the inclination; strong traction with the head extended (deflected) favors the development of palsies.

The Formation of Carcinomatous Metastases in the Ovary.—E. Kraus reports on the pathological histology of five cases of malignant disease of the ovary secondary to cancer of the stomach, colon, and bile passages, with a view to determining the avenue taken by the infective material. The conclusion is that the surface of the ovary is peculiarly permeable to even comparatively large foreign bodies, and that carcinomatous cells are capable of penetrating directly into it. When a primary tumor has destroyed the entire thickness of the wall of some organ and has broken through the serosa into the peritoneal cavity the younger elements on its surface are continually exposed to mechanical insult through the movements of peristalsis, respiration, etc., and particles are broken off and set free in the peritoneal fluid. Gravity brings these into the pelvis where they readily come into contact with the ovaries, the process being facilitated by the peritoneal irritation and consequent increased amount of secretion usually attending abdominal new growths. The penetration into the ovarian tissue is made possible by the nature of the germinal epithelium and the transplanted cells are greatly aided in gaining a foothold by the very highly developed lymph and vascular supply of the ovary.

Lo Sperimentale, No. 3, 1901.

Amyloid Degeneration Rapidly Developed During the Course of a Fatal Gangrenous Diphtheria of the Pharynx.—Carlo Comba reports a case in which amyloid degeneration was found in liver, spleen, and kidneys. The patient was a little girl of eight years, and her illness lasted eleven days only, during which time the degeneration must have developed. Whether this was due to the action of the diphtheria bacillus alone, or to that of other bacteria, or both, it is impossible to say with certainty. Further research to be undertaken by the writer may throw light upon the matter.

The Influence of Mechanical Causes on Bone Development.—Guido Bianchi concludes, from experimental researches, which consisted in paralyzing the muscles of the pelvis and lower limb of animals by section of the sciatic nerve, that the diminished growth of the bone which followed the operation was directly due to the absence of mechanical irritation from muscular contraction. This irritation of the periosteal tissues, he holds, causes the abundant deposit of bone tissue at the points of irritation. His conclusion is that muscular action is an important mechanical factor in the development and shaping of the bones.

Histological, Bacteriological, and Experimental Researches into the Nature of Rhinoscleroma.—Umberto Mantegazza holds that the Frisch bacillus is the pathogenic agent in this disease, not only because it is found in abundance in the affected tissues, but because, by its injection in animals, results similar to the process in rhinoscleroma have been obtained. Local methods of combating the affection are ineffectual from the difficulty experienced in reaching the seat of disease. Experimentation in future should be directed to the production of immunity in animals, in the hope that some means may be found of opposing the invasion of the bacillus in man.

The Pulse.—M. Mahillon says that the medical examiner must always keep in mind the following points when taking the pulse: A rate over 85 calls for the test of temperature, and if this prove to be over 98½° under the tongue, postpone the case, but at the same time examine very carefully the condition of the lungs. When the pulse remains from 96 to 100 during the whole of the examination, search minutely the circulation and respiratory systems and defer action. An abnormal slowness calls for postponement or rejection. Arhythmia of the pulse should claim special attention; neglect no search which may put you on the track for the cause and enable you to make a differential diagnosis. Hypotension is generally a serious symptom. It often implies organic heart lesions, and when continuous, diseases of the visceral organs, particularly nephritis, which may be confirmed by examination of the urine. Signs of atheroma and arteriosclerosis indicate an early senility and impose a refusal, or at least a limitation, of the risk, according to the age of the applicant. Absence of synchronism in symmetrical arteries should always be a cause for rejection.—*The Medical Examiner and Practitioner.*

The Use of Gelatin for Controlling Hemorrhage.—Joseph Sailer concludes from a study of the subject that 1. Gelatin increases the coagulability of the blood, whether applied locally, taken internally by the mouth, or injected subcutaneously or intravenously. 2. Applied locally it is usually harmless, but should always have some antiseptic added to it, so that it may not promote bacterial growth. 3. Injected subcutaneously or intravenously it is entirely harmless. 4. When administered by the mouth, from 100 to 300 grammes should be employed daily. 5. It is of advantage in any form of local hemorrhage, such as epistaxis, hemorrhoids, or injuries. 6. It checks certain forms of internal hemorrhage, such as hæmoptysis, hæmatemesis, metrorrhagia, and melæna neonatorum. 7. It is the best treatment for hæmophilia and is of use in purpura hæmorrhagica, and in hemorrhagic forms of infectious diseases. 8. At present it appears to be contraindicated in only one condition, viz., acute nephritis.—*The Therapeutic Gazette.*

The Treatment of Pulmonary Tuberculosis with Cinnamic Acid.—H. Staub's experiences with cinnamic acid and its salts are not as favorable as those described by Landerer, the originator of the method. A considerable number of patients were subjected to the treatment, and careful observations made to determine whether the alleged improvement really occurred, but the result was absolutely discouraging, and the conclusion reached is that the cinnamic acid therapy is without effect on the progress of tuberculous lesions, and that the good results ascribed to it are solely due to the accessory dietetic and hygienic measures employed. A slight tendency to the production of hæmoptysis was noted, but repeated blood counts did not show the leucocytosis which Landerer says is always present, and which forms the cornerstone of his theory as to how the agent produces its beneficial effects.—*Correspondenz-Blatt fur Schweizer Aerzte.*

Functional Significance of the Round Window.—A. Frutiger concludes an article on this subject as follows: 1. Whenever the oval window is greatly altered pathologically, and the lower tone limit much reduced, hearing for bass tones can be improved by using tampons to the round window membrane. This membrane, therefore, seems also to conduct sound from the tympanum to the labyrinth; under normal conditions, however, only such higher tones, perhaps from the small octave (inclusive) upward. 2. The round window membrane serves, normally, but chiefly in conjunction with the two aqueducts, to regulate the variations in tension of the labyrinthine fluids, namely: (*a.*) In case of wave movements produced in the labyrinthine fluids by tones passing through the chain of ossicles; (*b.*) In sudden shocks produced against the chain of bones by direct or indirect force.—*Archives of Otology.*

Book Reviews.

DISEASES OF THE STOMACH AND THEIR SURGICAL TREATMENT. By A. W. MAYO ROBSON, F.R.C.S., Member of Council and Hunterian Professor (1897–1900) Royal College of Surgeons, England; Senior Surgeon of the General Infirmary at Leeds, etc., etc., and B. G. A. MOYNIHAN, M.S., Lond., F.R.C.S., Assistant Surgeon, Leeds General Infirmary, Arris and Gale Lecturer (1899–1900), etc., etc. New York: William Wood & Co., 1901.

THE surgery of the stomach is always important and interesting enough to make communications from experienced surgeons of interest and value. This volume belongs to this class, and it is presented in a form which increases its value to a great extent. A preliminary chapter is given on the anatomy of the stomach, and the special methods of diagnosis when it is concerned, including exploratory incision, which the authors believe to be applicable to a small percentage of cases. In the pages devoted to gastrotomy a number of cases of extraordinary interest are described, and several astonishing collections of foreign bodies are illustrated. In their remarks upon gunshot wounds of the stomach, the authors say that the Transvaal war has shown beyond doubt that such wounds, when made by modern high-power small-arm projectiles, will heal without operative interference. This is a matter of great interest, and serves to accentuate the fatal character of such injuries occurring in civil life, which are usually made with revolver bullets, for which operation is always necessary. The simple tumors of the stomach, which are of few varieties, do not require much space for their discussion. They rarely come to operation, and those that do, are usually adenomatous. Carcinoma of the stomach and ulcer as the two most important diseases naturally need most attention. The symptoms and clinical history are very clearly given, and it is emphatically stated that our only hope of real benefit to the patient is early diagnosis and prompt surgical intervention in the presence of malignant disease. Considerable statistical material is introduced. The treatment of gastric ulcer is considered from a surgical point of view, and the hope expressed that surgical treatment will in future be resorted to more often than heretofore, as a matter of choice. The last third of the volume is occupied with descriptions of the operative technique of the operations upon the stomach, and the descriptions are terse and satisfactory. Total gastrectomy has arrived at the dignity of having statistics, and these are given. There have been twelve cases reported. The results of a large number of cases of gastro-enterostomy have been collected and are quoted. The illustrations are excellent, and some of the photographic reproductions of specimens are remarkable in their fidelity to actual appearances.

NERVOUS AND MENTAL DISEASES [By ARCHIBALD CHURCH, M.D., Professor of Nervous and Mental Diseases, Northwestern University Medical School, Chicago, and FREDERICK PETERSON, M.D., Chief of Clinic, Department of Nervous Diseases, College of Physicians and Surgeons, New York. Third edition, revised and enlarged. Philadelphia: W. B. Saunders & Co., 1901.

THIS book, which has been written as a textbook for medical students and general practitioners, has very well fulfilled the aim of its authors. In this, the third edition, as stated in the preface, the work has been thoroughly revised and many chapters have been rewritten and brought up to date. It really consists of two separate books under one cover, two-thirds of the 869 pages being devoted to the description of general diseases of the nervous system, while the remaining third treats of mental diseases only. The portion on nervous diseases by Dr. Church is divided into eight parts, viz., (1) Examination of patients, (2) diseases of the cerebral meninges and cranial nerves, (3) diseases of the brain proper, (4) diseases of the spinal meninges and spinal nerves, (5) diseases of the cord proper, (6) diseases of the general nervous system with known anatomical basis, (7) diseases of the nervous system without known anatomical basis, and (8) symptomatic disorders. This plan for presenting the subject, which is more or less adapted from the German school, is an eminently practical one and is systematically followed.

The treatise on mental diseases by Dr. Peterson is composed of eleven chapters, dealing respectively with the classification, general etiology, general symptomatology, examination of the patient, general treatment, and a description of the special forms of insanity. The entire field of psychiatry is treated in an interesting manner, the various clinical types being so clearly described as to simplify the matter for the medical student.

We do not hesitate in stating that the entire work is a creditable one, and that the authors are to be commended for the concise and practical manner in which they have dealt with the topic that is usually looked upon as the most difficult and abstruse branch of medicine.

INTERNATIONAL CLINICS. Edited by HENRY W. CATTELL, A.M., M.D., Vol. II, eleventh series. Philadelphia: J. B. Lippincott Company, 1901.

THIS quarterly of clinical lectures and especially prepared articles by leading members of the medical profession throughout the world comes this time with a colored frontispiece, illustrating the mild form of variola in a child, with groups resembling herpes febrilis. The article having especial reference to the prevalent epidemic is from the pen of Professor Schamberg of the Philadelphia Polyclinic, and is well illustrated. Some of the other articles are: Atony of the Stomach and Colon, Turck; Analgesia by Injection of Cocaine into the Spinal Column, Tuffier; The Oxytocic Effects of Above Process, Doléris; Puerperal Eclampsia, Jardine; Treatment of Malignant Tumors by Anticellular Serum, Wlaeff; Preventive Treatment of Hepatic Colic, Chauffard; Conservative Treatment of Appendicitis, Broca; Actinomycosis, Hektoen; Locomotor Ataxia, Frenkel; another by Allen Starr; Splenectomy, Wathen, etc., etc. A new feature is a list of newer medical words, with pronunciation and definition by W. A. Newman Dorland, the former editor. The general standard of the work is being well maintained.

LES PROCESSUS GÉNÉRAUX. Tome I. Histoire Naturelle de la Maladie, Hérédité, Atrophies, Dégénérescences, Concrétions, Gangrènes. Par A. CHANTEMESSE, Professeur de Pathologie expérimentale et comparée à la Faculté de Médecine de l'Université de Paris, Médecin des Hôpitaux; et W. W. PODWYSSOTSKY, Doyen et Professeur de Pathologie générale à la Faculté impériale de Médecine d'Odessa. Paris: C. Naud, 1901.

THIS is the first volume of a new work on general and experimental pathology, the joint production of the two pathologists of Paris and Odessa whose names appear on the title page. Chantemesse is well known to all students of and workers in experimental medicine in Western Europe and America, but Podwyssotsky has hitherto hidden his light under the Russian bushel, and is but a name to many pathologists. He is, however, the author of the best treatise on general pathology which has been written in the Russian language, and the scientists of the West are to be congratulated that this work is presented to them in understandable form. This new treatise is not a translation of Podwyssotsky's (better transliterated, Podvysotski's) former work, but follows the same general plan, although it is more complete and has also the advantage of Chantemesse's collaboration.

The authors start with the assumption of an almost imperceptible division line between physiological and pathological processes, and this idea is carried on throughout the work. Particular attention is given to cytology, and theories which are not based upon comparative and experimental pathology receive but scant notice. The volume begins with a study of the natural history of disease, or rather of the morbid processes observed in man, and this is followed by a discussion of the general etiology of disease, especial attention being paid to heredity in its cytological, physiological, and pathological relations. Then the authors take up the subject of atrophic processes dependent upon disturbances of cellular nutrition, among which are included the various forms of degeneration—parenchymatous, hyaline, amyloid, colloid, fatty, pigmentary, glycogenic, etc. This part includes also a study of the formation of biliary, urinary, intestinal, and bronchial calculi, and exogenous deposits following the inhalation of various dusts or the ingestion of certain medicaments and other substances. The volume closes with a consideration of the different varieties of gangrene. The second volume, which is promised within the coming year, will be devoted to a study of hypertrophies, tumors, the regeneration of organs, the pathology of the blood and lymph circulatory systems, inflammation, and fever.

The illustrations are deserving of special mention and commendation. They are beautifully executed, many of them being printed in colors, and are said to be faithful reproductions of Podwyssotsky's original sections, which we can well believe they are.

SYPHILIS; ITS DIAGNOSIS AND TREATMENT. By WILLIAM S. GOTTHEIL, M.D., Professor of Dermatology and Syphilology, New York School of Clinical Medicine; Dermatologist to the Lebanon and Beth-Israel Hospitals, the West Side German Dispensary, etc. Chicago: G. P. Engelhard & Company.

THE author here gives in a concise manner (216 pages) the main facts connected with the study of a most important condition. It is a work more suited to the general practitioner than to the needs of the student. There are a number of good original wood cuts. The author's personal views are nicely blended with those held in general upon the various questions discussed.

THE TREATMENT OF FRACTURES. By W. L. ESTES, A.M., M.D., Director and Physician and Surgeon-in-Chief of St. Luke's Hospital, South Bethlehem, Pa. New York: International Journal of Surgery Co.

THIS is one of the most practical little books we have seen, and one which the young practitioner, especially in the country, where the advice of older heads is not always available in an emergency, can ill afford to be without. It is not a general treatise on fractures, for the author has confined himself strictly to his subject as announced in the title, and seldom wanders off into a discussion of the signs or the causes of special forms of breaks in bones. But within his self-imposed limits he does not sacrifice clearness of description to brevity, the directions for treatment being complete in every detail, leaving nothing to be understood by the reader beyond the necessary adaptation of general directions to individual cases. The work has all the charm of originality, as far as this quality can be associated with so old a subject, the author having drawn upon the fund of his ripe experience rather than making a digest of others' writings. The illustrations are numerous and good.

CRAZES, CREDULITIES, AND CHRISTIAN SCIENCE. By CHARLES M. OUGHTON, M.D. Chicago: E. H. Colegrove, 1901.

THIS is a handy little volume, containing in a few pages many points which may be used to advantage by those arguing in support of sanity as opposed to "Christian Science." The aim of the author, he says, has been "to submit a timely, healthful, and interesting thesis for intelligent readers still in possession of open minds and common sense," and this he has succeeded well in doing. A table of contents would be of service, to enable one who had once read the book to refer to any particular point on which he would refresh his memory.

PRACTICAL FIRST PRINCIPLES. Simplifying the Study of Normal and Abnormal Structure and Function, and Aiding Diagnosis. Designed for the Use of Students and Practitioners of Medicine. By A. H. P. LEUF, M.D., Associate Editor of the *Medical Council*. Philadelphia: The Medical Council. 1901.

IN this little book is contained a vast amount of information on cytology—the anatomy, physiology, and pathology of the cell, and through it of the human organism. Beginning with a consideration of the protamœba, or mass of undifferentiated protoplasm, the author studies in regular sequence the cells, cell-compounds or tissues, tissue-compounds or organs, and then the body as a whole; after which he demonstrates cellular nutrition, physiology, and pathology, and the practical application of the general principles previously enunciated. A brief exposition of medical nomenclature is added, and the book closes with a description of the microscope. We know of no book which could better be put into the hands of an intending student of medicine, and if he once mastered it the benefits of the knowledge so gained would be apparent at every stage of his college course. Many old graduates will also find it of great service as a refresher of the memory.

ANÆSTHETICS AND THEIR ADMINISTRATION. A Textbook for Medical and Dental Practitioners and Students. By FREDERIC W. HEWITT, M.A., M.D., Cantab. Anæsthetist to His Majesty the King, Anæsthetist and Instructor in Anæsthetics at the London Hospital. With illustrations. London: Macmillan and Co.; New York: The Macmillan Company, 1901.

WHILE it is true that, for a number of years, increasing attention has been devoted to the subject of anæsthesia and especially its dangers and the methods of avoiding them, it must be admitted that progress has been somewhat slow and several much needed reforms are still in the visionary stage. It has been too long a matter of tradition to regard the anæsthetizer's function as the simplest at an operation and in most hospitals this duty is still relegated to the youngest and most inexperienced member of the staff, and the schools similarly slur over the discussion of this subject by making it merely an incidental in the teaching of materia medica. While the time is undoubtedly coming when a course in anæsthesia, practical and theoretical, will form part of every medical curriculum and be a requisite for graduation, the average practitioner is also in need of enlightenment and for the reader to whom "anæsthesia" means simply chloroform or ether forced upon a patient till insensibility is produced the present volume will come as a revelation. It is truly a monograph on the subject and presents an immense amount of information, every bit of which is practically useful, however, and of vital importance to any one desirous of conducting his patients comfortably, as well as safely, through their anæsthesias. There are five general headings under which are considered, respectively, the history, pharmacology, and experimental physiology of general surgical anæsthesia; preliminary considerations before anæsthetization; the administration; the management and treatment of the difficulties, accidents, and dangers of anæsthesia; and the condition of patients after the administration. The author is particularly to be commended for his insistence on the necessity of strict individualization and has discussed the contingencies of practice so fully that it is hard to conceive of a case for which the proper combination and sequence of anæsthetics is not indicated. That this requires a certain amount of judgment is evident when one considers that he treats of eleven different types of anæsthesia, viz., by nitrous oxide, ether, chloroform; A. C. E. mixture; C. E. mixture, nitrous oxide and ether; A. C. E. and ether; ether and chloroform; nitrous oxide, ether, and chloroform; A. C. E. (or C. E.), ether, and chloroform; and A. C. E. and chloroform, each of which has its special indications and contraindications which are clearly explained. The various forms of inhalers, mouth gags, tongue forceps, etc., are critically discussed as well as the position of the patient and the methods of treating possible accidents.

CHIRURGIE GASTRO-INTESTINALE. Par HENRI HARTMANN, Professeur agrégé à la Faculté de Médecine, etc. Paris: Georges Steinheil, 1901.

WE had occasion to review some time ago a book by this author, in collaboration with Terrier, on the surgery of the stomach, and we are glad to be able to commend this later work by one author. The monograph is devoted to the surgery of the stomach and intestine, and occupies itself chiefly with the more recent advances in this field. There is a well-illustrated preliminary chapter on the anatomy of the stomach and the upper part of the intestine, and then some space is devoted to an historical review of the subject. All the various methods of excising the pylorus are described and illustrated, and the other gastro-intestinal operations receive attention, among which gastrectomy gets its share. There are numerous good illustrations of the different methods of making intestinal anastomosis, and a chapter is devoted to the performance of colotomy, which is worth attention. The last chapter is occupied with the consideration of the various methods of removal of the rectum when it is the seat of malignant diseases. It contains much useful information, concisely given, and some good explanatory diagrams.

A TEXT-BOOK OF THE PRACTICE OF MEDICINE. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of the Practice of Medicine and of Clinical Medicine in the Medico-Chirurgical College, Philadelphia; Attending Physician to the Medico-Chirurgical and Samaritan Hospitals, Philadelphia, etc. Fifth Edition. Philadelphia and London: W. B. Saunders & Company, 1901.

THE fact that a revision of this work has been called for within less than a year since the appearance of the fourth edition gives sufficient evidence of the place accorded to it in the medical world. The book is divided into eleven parts, filling 1,297 pages, the index taking up twenty-nine pages. Particular attention is paid to etiology, diagnosis, and treatment. In connection with etiology, bacteriology is emphasized. Fully fifty-six diagnostic tables are scattered through the text, a large number of them being original. Valuable formulas are given throughout the book, both the English and metric systems being used. Modern views have necessitated changes in certain parts, the sections on malaria and yellow fever requiring special alteration. Several new articles have been added, among which are papers on streptococcus pneumoniæ, acute diffuse interstitial nephritis, and fatty infiltration. The illustrations, though not numerous, are good.

THE DISEASES OF THE RESPIRATORY ORGANS, ACUTE AND CHRONIC. Arranged in Two Parts. By WILLIAM F. WAUGH, A.M., M.D., Professor of Practice and Clinical Medicine, Illinois Medical College, etc. Chicago: G. P. Engelhard & Company, 1901.

THIS book of 221 pages is arranged in two parts, the first being devoted to the consideration of acute respiratory diseases, and the second to that of the chronic forms. The author states in his preface that his object in preparing this work was his belief that the treatment of acute respiratory diseases has gone beyond what is found in the general textbooks on the practice of medicine. He believes that the treatment of these diseases in the future will be concerned with the part played by the vasomotor nerves in acute inflammations, and the effect of drugs upon these nerves, rather than with the study of the diseases as pathological entities. There is much in this. The book is concise, and has many points of value for both physician and patient.

Clinical Department.

A DAY AT THE CLINIC OF HIPPOCRATES.

W. C. CAHALL, M.D. EDITOR.
GERMANTOWN, PA.

TO THE HIGH PRIEST AND FELLOWS OF THE TEMPLE OF ON. HEALTH!

I HAVE now been sufficiently long with this great master of medicine to make to you my first report. When I left you at the end of the Feast of the Overflowing Nile, I proceeded to the sea, expecting to there await some wheat-ship bound for Greece. I sojourned with our brethren at the little temple at the mouth of the Nile. When I told them that my mission to Greece was to study the methods of Hippocrates, whose fame was sounding throughout the world, and to report to our priesthood by what favor of the gods he has grown so great, one of the priests informed me that he had been called that very morning to see and give temporary aid to a sick nobleman, who was upon his galley in the river beyond the temple, outward bound to see this same physician, and that, if I would go with him on his next visit, in the morning, he thought I might be taken to Greece with him, as his ship physician.

This was readily agreed to by the owner of the galley, for he proved to be the Governor of Thebes, who, you will remember, spent several weeks at our temple for a shortness of breath and pain in the left side, and which resisted all our baths, our most solemn exorcisms, even the gilt bull which we had painted on his side. He believes now, as we told him at the time, that he is possessed by a demon, which does not acknowledge the authority of our gods, and now goes to Greece with the hope that the gods, of whom Hippocrates is a priest, will be able to cast it forth.

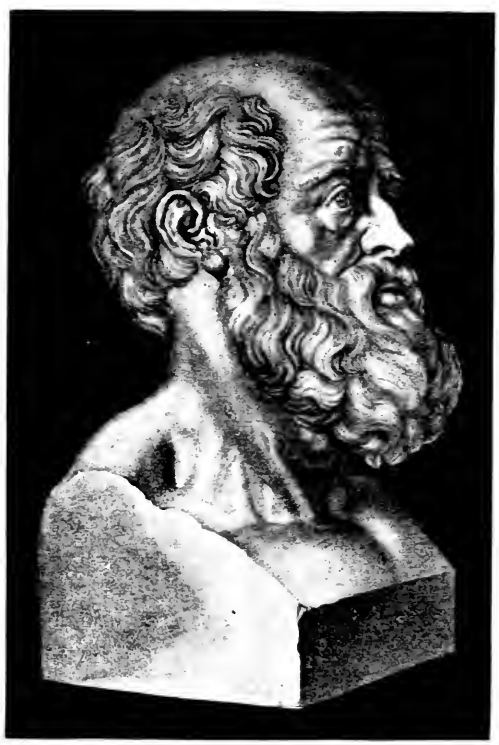

FIG. 1.—Hippocrates.

Our voyage to the island of Cos was uneventful, but we were obliged immediately to reship to Athens, for we found that Hippocrates had gone to that city by the invitation of the Athenians, because of a frightful plague, which was depopulating the country. By the time of our arrival he had gotten it under control, but we arrived in time to witness the extraordinary proceedings of his public reward. Besides large gifts of gold, he was presented in the public assembly with a golden crown, and, greater than all, with Athenian citizenship. And what, think ye, he did to win this great honor?

After the Athenians had marched in innumerable processions to their temples and offered holocausts to appease their gods, Hippocrates simply directed ditches to be dug and bonfires built of aromatic branches; not a procession, nor a sacrifice. He said the plague was caused by bad air, while we all know that the air is filled with evil spirits which afflict human bodies.

Because of my knowledge of Greek, my patron kept me with him. We secured lodgings with Kriton by the Well of Phrynichides. It was well for me that such arrangements were made, for because of his influence and rich gifts to the altars, I had especial facilities accorded me for studying Greek medicine.

I find that these temples of health, as they are called, scattered throughout Greece and her colonies, are under the control of one family of priest-physicians, the Asclepiades, who show scant courtesy to foreign students.

The ritual of these temples, like all others I have seen in Greece, is very beautiful, though inferior to our ancient service in solemnity and impressiveness. Many points in practice and more in philosophy were taken from us. This is not at all strange when you recall that many of their greatest teachers and students have been accustomed to visit our temple schools for study. Indeed, I was much surprised to learn that even the Great Mystery, so jealously guarded by our priesthood, of the unity of God is known here, and openly taught by their greatest philosophers.

The Temple of Asclepios at Athens and its precincts occupy a most salubrious location on the southern slope of the rock of Acropolis, protected from the cold winds from the north and exposed to the warm sun, and at an elevation of about eighty feet above the plain. The Propylæa, the great ceremonial gateway to the sacred precincts, with its columns and decorated frieze, prepares the visitor for surprising beauties within.

Through this gate the motley crowd of sick enter; the poor man with his crutches, a blind woman led by friendly hands, a group of slaves with their supervisor, a Thracian warrior with a poisoned arrow in his body, a pair of athletes to receive a lesson in dietetics, a Jew with oiled locks and a knowing smile, a rich merchant on his litter, or some nobleman, like my patron, having a procession of his own, with his slaves, bearers, and armed guard: such was the human tide which I saw ebb and flow through this gate every day.

Within the gate one sees a forest of columns, upholding each temple and lining the colonnades, incomparable for proportion and grace. Allegorical scenes, in carving and color, decorate every cornice, frieze, and architrave, and innumerable altars and statues line the walks from temple to temple. Nor is the service less beautiful than the buildings. The ritual is highly poetical and the singing of the priests unlike anything heard in Egypt. Such ceremony, in such surroundings, puts the mind and body in a condition most favorable to receive the full benefits

FIG. 2.—Æsculapius.

of the use of the healing springs, the baths, the dietetics, and the gymnastics prescribed here, and these priest-physicians have shrewdly worked for that end.

I send enclosed a sketch of the grounds and principal buildings.

Upon entering, the patient is conducted by one of the Kleidouchoi or key-bearers to the Hiereus or High-priest, or one of his officials, the Hieromnemones, to arrange the financial terms of his treatment and accommodation. Then come the rites of purification, the bath in the sacred fountain, the change of linen, the offering of the sacrifice upon the altar. Here an interesting part of the ceremony takes place. One of the Pyrophoroi, bearing the sacred fire, lights the altar, the patient presents his offering—a cake if he is poor, a sheep or goat if he is rich—and places his hand upon the altar, while the priest chants his invocation for succor and health on behalf of the applicant. If at this juncture, one of the temple dogs or a sacred serpent, which are believed to incarnate the god, should come up and lick the diseased spot, it is a happy omen.

Led by the Dadouchoi, the torch bearers, and the singers, the procession then enters the temple of Asklepios through an ivory door, which alone cost thousands of drachmæ. Here sits upon his throne the gigantic statue of Asklepios, whose flesh is of ivory, and garments of gold enameled in colors, and having on his right hand a crouching dog, upon his left a golden serpent, while before him is an altar where further rites were performed.

At nightfall each patient spreads his bed upon the floor or upon the low couches in the abaton, a long portico or corridor-like building, open to the air. Here gifts are laid upon the altar, the fire is lighted, the priests recite the evening prayer for the healing visitation of the god in dreams or visions; the gifts are collected, the fires extinguished, and quiet and sleep enjoined.

During the day, if he is physically able, the patient has many sources of recreation—baths, friction, gymnastics, walks in the shady groves, visits to the various temples, plays in the theater of Dionysius, and the contests in the Stadium outside the precinct; while for the less actively inclined, the bronzes, the encaustic painting, the fountains, a manuscript from the library, the music, the public readers, and the countless votive tablets.

The time goes rapidly enough. Surely the god of beauty broods over these Greeks. I shall not surprise you when I tell you that a short season of this life cures many of these votaries without further medicine. Should, however, the case be found urgent by the examining priest-physician, or if no improvement follows such an introduction, the chief physicians are consulted. It was by such gradual steps that my patron advanced to the clinic of Hippocrates.

A man past middle life, the great dome of his head partially bald, long beard, and heavy eyebrows, the nose smaller and more broken at the brow than the typical Greek nose, the eyes large and lustrous, the face of Hippocrates expressed great benignity, energy, and wisdom.

Hippocrates uses the purest Ionic dialect, and speaks, as he writes, in a condensed yet luminous style. His aphorisms are as famous as any of the sayings of Socrates.

Such was the man we saw, upon our arrival, standing amid a group of white-clad priests and students, expounding to them the principles and methods of medicine as he understood it. As we entered, he was engaged with a slave woman, who had been poisoned by eating mushrooms. A few, swift ques-

FIG. 3.—Hygeia and Æsculapius.

tions put him in possession of the cause of the symptoms. An emetic was administered, followed by a hot bath, and the woman, already with cold extremities and sunken face, recovered. This led him to mention the value of the appearance of the countenance of the sick, and he repeated what is one of

his most famous prognostics: "If the patient present the following features at the beginning of an acute disease, and no removable cause be discovered, it is to be known for certain that death is at hand: a sharp nose, hollow eyes, collapsed temples; the ears cold, contracted, and their lobes turned out; the skin about the forehead being rough, distended, and parched; the color of the whole face being green, black, livid, or lead-colored; when the lips are relaxed, pendent, cold, and blanched."

The next case he examined was that of a wounded soldier with spear wounds on his head and knee-joint.

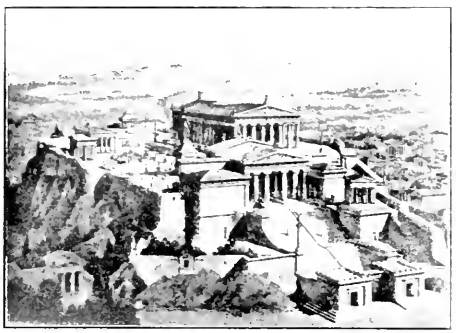

FIG. 4.—The Acropolis at Athens. [Restoration.]

Among his observations were these: "The most dangerous wounds are those which implicate the large blood-vessels in the neck and groin; then those of the brain and liver; next those of the bowels and bladder. These cases are all dangerous, but not uniformly fatal as some suppose. Large wounds of the joints leave the limb maimed."

Several other observations connected with these injuries are added, of which one of the most important is the direction to practise flexion and extension of the limb, frequently, with the view of preventing rigidity of the joint.

Since the head injury was the more severe he had to trepan the soldier's skull. The instrument he used was a circular one with a serrated cutting edge, and quickly removed the bone down to the meninx. With an elevator he raised the depressed bone and removed the clots. He used no liquid applications, or plasters, or stitches, or tents to wounds of the head, but filled the wound with a cleansing paste in order to hurry healthy granulations.

Among the many clinical observations on the injuries to the head I recall these as being the most striking: the larger the fracture the less concussion to the brain; if you cannot discover whether the fracture be present or not, you must dissolve the jet-black ointment and fill the wound with it when thus dissolved, and apply a linen rag smeared with oil, and then a cataplasm of the maza with a bandage. On the next day, having cleaned out the wound, scrape the bone with the raspatory. If the bone is not sound, but fractured and contused, the rest of it which is scraped will be white, but the fracture and contusion, having imbibed the preparation, will appear black. A bone may be injured in a different part of the head from that on which the person has received the wound, and the bone has been laid bare. And for this misfortune, when it occurs, there is no remedy; for when this mischief takes place, there is no means of ascertaining by any examination whether or not it has occurred, or on what part of the head.

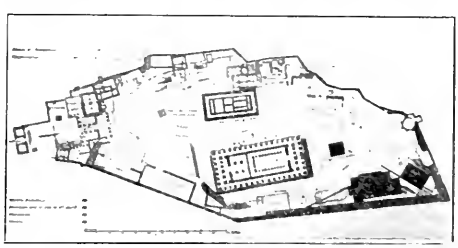
This claim that a blow on one side of the head may give rise to a fracture and hemorrhage on the opposite side has been much disputed, but Hippocrates has fortified his position by the examination of the bodies of the injured after death. Indeed, so far does he go to make his knowledge exact, that he has in his chambers at Cos a complete human skeleton.

The next case was also that of a slave, with a sprained and swollen joint. This case afforded him a text to speak upon the effects of hot and of cold water. "Cold water," he says, "inflames ulcers, burns, fractures, and luxations. The parts of the body which are usually covered endure the cold water worst, and are most refreshed by hot. Cold water disagrees with the brain and its processes, the bones, the teeth, and the nerves; and hence convulsions, distensions, and febrile rigors, which are induced by cold, are relieved by hot water. Hot water occasions delight and determination to the skin; cold, on the other hand, pain and determination inwardly; wherefore the loins, the breast, the back, and hypochondriac region are injured by cold applications, but delight in warm."

Next came two athletes, training for the games, one for relief of a sprained shoulder, and the other for instruction as to diet while training. After attending to their needs, Hippocrates expressed himself upon athletics, regretting the tendency of the times to special training for special prizes.

He said that formerly it was the custom for an athlete to develop all his body, and enter the contests for various prizes, so that it was not unusual for one man to win several prizes, such as javelin throwing, hurdle jumping, with and without armor, wrestling, and running, at the same games. Now the palestræ were becoming schools of training for one contest, necessarily developing the athlete unsymmetrically instead of into the well-balanced and beautiful forms so constantly seen in the older Olympic games.

He next took up a child suffering from club-foot, in which he pointed out to us his reasons for denying the existence of a dislocation of the joint, but only a declination of the foot, and demonstrated to us his



PLAN OF THE ACROPOLIS AT ATHENS.

method of systematically bandaging the foot during infancy, whereby a cure could be effected without surgical operation.*

* "In fact, until within a very recent period, the modern plan of treatment in such cases was not at all to be compared with his skilful mode of adjusting fractured bones, and of securing them by means of waxed bandages. In particular, his descriptions of the accidents which occur at the elbow and hip-joints will be allowed, even at the present day, to display a most wonderful acquaintance with the subject. In his views with regard to the nature of club-foot, it might have been affirmed of him a few years ago, that he was twenty-four centuries in advance of his profession when he stated that, in this case, there is no dislocation. In a word, until the days of Delpech and Stromeyer, no one entertained ideas so sound and scientific on the nature of this deformity as Hippocrates."—Dr. Francis Adams.

At this point he was disturbed by a young woman, waiting her turn for consultation, who suddenly fell down on the stone pavement in a fit, screaming and gnashing her teeth, her body in a bow, resting on her heels and back of the head. She was supposed to be suffering from the sacred disease.

Hippocrates raised her eyelids, but nothing save the white of the eyes could be seen. His examination was brief, and I thought I detected a smile behind his beard. He arose and said in a loud voice, so that the patient could hear, "The eyes must be brought back to their proper position and then the fit will end. Bring forth the sacred serpents, and have them lick the eyes of this young woman, and she will be restored."

Before the serpents could be brought the young woman arose from the ground, cast an indignant glance at the teacher, and sailed out of the temple court. Hippocrates then made the laconic remark that so potent are some remedies that the mere promise of them is sufficient to cure.

In contrast to the school of Cnidos, his great rival, where diagnosis is made the chief object of study and made cumbersome by its very refinement, Hippocrates has elaborated prognostics. He asks, "How can one know the effects of treatment until he knows the natural history of disease? Knowing this and likewise the effects of drugs, the outcome of the disease, whatever its name, may be approximated, and, after all, this is what most concerns the family of the patient."

There are certain signs and symptoms common to many diseases, some of which indicate recovery, and others which prognosticate death, and these the wise physician looks for. I have been witness to some of these shrewd prognostics of Hippocrates, which sounded, indeed, like divination, but which he declares are the result of clinical observations. He does not claim originality for all his observations. Many of them belong to his family traditions, but even these he has modified, amplified, and made more exact. These, together with what he has himself observed, he has embodied in his book on prognostics, a copy of which, together with many others, I have, and which I will present to our temple library on my return. I will, in this letter, give but one extract from this book, which will indicate the extraordinary wealth of observation contained in it:

"Respecting the movements of the hands, I have these observations to make: When in acute fevers, pneumonia, inflammation of brain, or headache, the hands are waved before the face, hunting through empty space, as if gathering bits of straw, picking the nap from the coverlet, or tearing chaff from the wall—all such symptoms are bad and deadly."

Many other deeds of wonder did this great physician before us, but I must postpone recounting them until my return. I will mention, however, the case of my patron. Had I seen nothing else than his conduct of this one case, I would have been amply repaid for my journey.

Hippocrates carefully examined and questioned my patron. He then performed a manœuver unknown to Egyptian medicine. He applied his ear to the patient's chest, struck the side with his hand, and shook the patient. Whereupon he declared there was fluid in the patient's chest. This manœuver he asked me to repeat after him, when I distinctly heard a splashing sound, like water in a half-empty bottle. Hippocrates then said that, judging from the length of time my patron had been sick, the character of the fever, and the sweats, he was of the opinion that the fluid was purulent. Taking up his lancet, he pierced the side, and out flowed a large quantity of greenish-yellow matter, just as he predicted.

The operator remarked, with evident care to his words, for it was an unprecedented thing for a priest to say, that, however divine diseases may be in their origin, they had a natural history, affected bodies subject to physical laws, that it was but rational to resort to physical means for cure, and that, for instance, a thousand painted bulls were not as efficient as one lancet thrust.

The priesthood received this remark with many scowls of dissent, and I have seen much to support the belief that nothing but the overpowering pre-eminence of the great Hippocrates saves him from banishment, if not from death. But that he is not an irreligious man was shown by his very next act. This was the administration of the oath, which he himself directed at the conclusion of the clinic.

A class of young priests who were to devote themselves to the practice of medicine, who had already gone through a form of purification and sacrifices in the more secret temples, and which I did not witness, came marching in a procession of white, chanting their beautiful choruses, and bearing the incense and their serpent-twined statue of Asklepios. They circled the little altar, before which Hippocrates stationed himself; each, with sandals removed and right arm bare and outstretched toward the altar, took the following beautiful and noble oath, worthy of the great physician who composed it and of the young lives devoted to it:

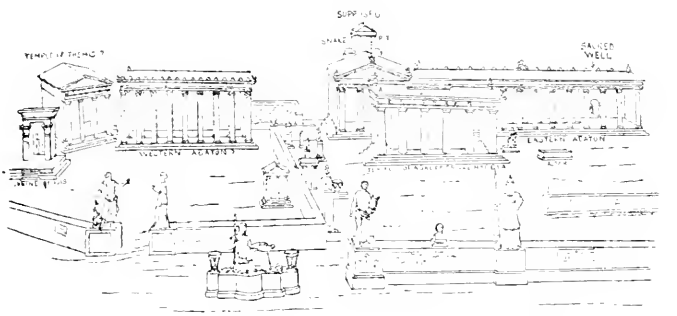

FIG. 6.—Attempt at an Outline Restoration of the Asklepeion at Athens.

THE HIPPOCRATIC OATH.

"I swear by all the gods and goddesses, by Apollo the physician and Asklepios, and Health and All Heal, that I will keep this my oath and stipulation—to reckon him who taught me this art equally dear to me as my parents, to share my substance with him and to relieve his necessities, if required; to look upon his children as my brothers, and to teach them this art if they shall wish to learn it—and that by precept, lecture, and every other mode of instruction, I will impart a knowledge of the art to my own sons and those of my teachers, and to disciples bound by a stipulation and oath according to the law of medicine, but to none others. I will follow that practice which, according to my ability and learning, I consider the best for the safety of my patient, and

abstain from whatever is deleterious and mischievous. I will give no deadly medicine to any one, if asked, nor suggest any such counsel; nor will I conspire with a woman to destroy her unborn child. With purity and with holiness I will pass my life and practise my art. Into whatever house I enter, I will go into them for the benefit of the sick, and will abstain from every voluntary act of mischief and corruption, and, further, from the seduction of women, whether bond or free. Whatever, in connection with my professional practice, or not in connection with it, I see or hear in the life of men which ought not to be spoken of abroad, I will not divulge, thinking that all such should be kept secret."*

A man cannot become great without finding enemies, who hate him for his very greatness. Hippocrates has not escaped the fate of greatness, and he has been accused of setting fire to the library at Cos, to destroy the medical records there in order to claim for himself originality for observations which he in reality borrowed from the ancients. That he profited by the careful study of these volumes of detached and unclassified records he would be the last to deny; but that it was necessary to destroy these records and votive tablets in order to display his superiority may be seen by comparing the character of the average votive tablets, a few of which I have copied here and at Epidaurus, and here reproduce, and a few of the aphorisms of Hippocrates, surcharged as they are with the highest wisdom, checked and rechecked by experience.

Votive Tablet 12.—*Case of a man*, who came to the god as a patient; he had but one eye; of the other only the empty eyelids remained, and some of those in the precinct said it was sheer folly for him to suppose that he could see, when he had no vestige of an eye, but only an empty socket. While he slept he saw a vision; it seemed to him that the god mixed a salve, and opening his eyelids poured it in. And when day broke he departed seeing with both eyes.

Tablet 120.—*Case of Alcebas of Halica.* He was blind and saw a vision; he thought the god approached him, and with his finger opened his eyes, so that he could see the trees in the precinct. And when day broke he departed cured.

Tablet 125.—*Case of Thyson of Hermione*, a blind boy, who being licked while awake by one of the temple dogs on the eyes departed cured.

Tablet 68.—*Case of Euphanes, a boy of Epidaurus.* He went to sleep suffering from stone. And it seemed to him that the god stood by him and asked, "What will you give me if I make you well?" And he answered he would give ten knuckle-bones, at which the god laughed, and said he would ease him. And when day broke he departed cured.

Tablet 41.—*Case of a dumb boy.* He came to the precinct to ask a cure of his dumbness; when he had made the preliminary sacrifice and performed the rites, the slave of the god who carried the torch turning to the father of the boy said, "Do you promise that if within a year he gains the end for which he came he will make sacrifice of thanksgiving?" And the boy suddenly answered, "I promise"; the father in astonishment bade him say it again; and he said it again, and thenceforward was cured.

Tablet 111.—*Case of Nicanor*, a lame man. While he was sitting awake a boy snatched away his crutch and began to run off; he jumped up to pursue and was thenceforth cured.

*In some of the European schools this oath is still administered to the young candidate for medical degrees, but, whether actually sworn to or not, everywhere that men graduate in medicine, the moral import of this oath is still supposed to rest upon the practitioner of medicine. —W. C. C.

Tablet 95.—*Case of Enippus.* He carried a spearhead six years in his jaw; when he was laid to sleep the god extracted the spearhead and gave it into his hands. And when day broke he came forth cured, carrying the spearhead in his hand.

Tablet 107.—*Case of Hermodicus.* He was paralyzed; sleeping, he was cured by the god, who bade him go out and bring into the precinct the biggest stone he could carry; so he brought in the stone, which still lies before the hall.

Tablet 113.—*Case of a man*, whose toe was cured by a sacred serpent. His toe was in pain from the bite of a wild beast; he was carried outside by day by the temple servants, and was sitting on a seat, when he fell asleep; and while he was asleep a snake issued from the hall and cured his toe with its tongue, after which it returned to the hall. He, awaking cured, said he had seen in a vision a beauteous youth pouring medicine on his toe.

Tablet 122.—*Case of Heræus of Mytilene.* He had no hair on his head, but a good crop on his chin; being ashamed of being a laughing-stock of his companions, he came to sleep in the hall; and the god anointed his head with salve, and made the hair come.

Tablet 98.—*Case of a man* who was cured of leeches. He slept in the hall and saw a vision; he thought the god cut open his chest with a knife, and taking out the leeches gave them into his hands, and sewed up his chest again. When day broke he departed carrying the creatures in his hands, and was cured. He had swallowed them in consequence of a stepmother's trick, who had put them into a potion which he swallowed.

Tablet 3.—*Case of Cleo*, who went five years with child. She, in the fifth year of pregnancy, came to seek aid of the god and went to sleep in the hall; and no sooner did she come forth from it and pass outside the precinct than she gave birth to a son, who, directly after birth, washed himself at the spring, and began to walk about with his mother. And after meeting these fortunes she wrote upon a votive tablet, "Not the size of the picture but the miracle is the marvel, that Cleo bore the burden in her womb for five years, till she slept here and the god made her whole."

Tablet 22.—*Case of a man*, whose fingers were paralysed, all but one. He came to the god to seek aid, but looking round at the votive tablets of the precinct he was doubtful about the cures and began to ridicule the inscriptions. He slept in the hall and saw a vision; he thought that he was playing with astragali close to the temple, and was going to cast; the god appeared and seemed to seize his hand and stretch out the fingers of it. And when he went away he thought he clenched his hand and then extended all the fingers; the god asked him if he was still sceptical as to the inscriptions on the votive tablets in the temple; and he replied that he was not.

Tablet 33.—*Case of Ambrosia* from Athens, who had but one eye. She came to seek aid of the god; and walking round the precinct, began to ridicule some of the cures, saying it was absurd and impossible that the lame and the blind should become whole merely through seeing a vision. And sleeping, she saw a vision; she thought the god stood by her and said that he would make her whole, but she must for payment dedicate in the precinct a pig of silver, as a memorial of her folly. And with these words the god cut open her diseased eye and poured a drug in. And when day broke she went away healed.

Tablet 90.—*Case of Æschines.* When the suppliants were laid down to sleep he mounted into a tree and pried into the hall; and he fell from the tree and struck his eyes on some palings. Being in an evil

case and having become blind, he turned as a suppliant to the god; and he slept and became whole.

APHORISMS OF HIPPOCRATES.

In all kinds of fevers, and other diseases, voluntary tears be laudable, but if they flow contrary to the patient's mind, they are to be feared.

To have a convulsion with a sore wound is death.

To dote or be distrait, after a blow, is very evil.

Whosoever hath his brains hurt in any way doth suddenly lose his speech.

He that spitteth frothy blood is diseased in his lungs.

The frenzy in a peripneumonia is an evil token.

They who are between eighteen and twenty-five are chiefly troubled with consumption.

Eunuchs be never bald nor gouty.

It is much better that he which hath a convulsion be taken with an ague than he which hath an ague be taken with a convulsion.

The patient must forbear meat in the fits.

Unto extreme diseases extreme remedies are necessary.

Contraries or opposites are remedies for each other, evacuation for repletion, repletion for depletion; when we do anything according to reason, we should not too hastily alter our plan so long as the reasons for continuing it remain unaltered; we should observe what gives ease and what gives pain, what is easily borne and what cannot be endured; we should do nothing rashly, but often pause for observation, since in this way we at least do no harm.

It is the mission of the physician to do good, at least to do no harm.

Life is short; art is long; the occasion fleeting; experiment dangerous; judgment difficult. The physician must not only do what is right himself, but also to make the patient, attendants, and externals cooperate.

Many strange and wonderful things have I seen and learnt at this clinic of Hippocrates, but I withhold them until I see you. BAK-EN-KHONSU.

Society Reports.

ROCKY MOUNTAIN INTERSTATE MEDICAL ASSOCIATION.

Third Annual Meeting, Held at Denver, September 3 and 4, 1901

THE meeting was called to order by Dr. C. K. FLEMING, the President. An invocation was offered by Dean H. M. Hart of Denver, and a welcome by Mayor Wright of Denver.

Ocular Lesions of Chronic Interstitial Nephritis and Their Significance.—Dr. E. JACKSON of Denver read a paper on this subject. He called attention to the value of the ophthalmoscopic appearance of the arteries and veins of the retina in the early diagnosis, as well as in the prognosis, of this disease. He said it was not yet settled whether the local renal condition was a cause or effect of the general vascular state. The notable things in the early stages, as revealed by the ophthalmoscope, were minute hemorrhages, œdema, exudations, and sacculation and irregularities in the caliber of the vessels. Changes in the walls of the vessels appeared as opacities and grayish or whitish lines. Small retinal hemorrhages were common, and he considered their rapid absorption and disappearance favorable in the prognosis. After imperfect absorption, whitish patches radiating from a macula might be seen; this indicated high tension and failure of elimination, and was decidedly unfavorable.

Carcinoma of the Breast.—Dr. D. A. RICHARDSON of Denver read this paper. He believed trauma to be the cause and not inheritance. He reported an instance of two sisters, following similar occupations, who were afflicted, while in the family of fourteen children, a history covering forty-three years showed no other cases.

Epileptic Anamnesia.—Dr. S. D. HOPKINS of Denver reported a medico-legal case of epileptic anamnesia, and pointed out the differential diagnostic points between true and feigned anamnesia.

Dr. J. T. ESKRIDGE of Denver, in the discussion of this paper, said that the claim of total anamnesia in a criminal case should arouse suspicion of malingering, while names and remote events may be forgotten, details connected with the personality are apt to be recalled, and events recur to the mind in the inverse order in which they were lost from memory.

Resection of the Superior and Middle Cervical Ganglia of the Sympathetic for Subacute Glaucoma.—Dr. MELVILLE BLOCK of Denver read a paper with this title, and showed the patient on whom the operation was done. The trouble was on the left side; there was pain in the left eye, impaired vision, rainbow hues about objects, increase of tension, and slight prominence of the ball; eserine relieved these symptoms temporarily. The operation done by Dr. Parkhill of Denver relieved these symptoms almost immediately. Six months after operation there are no symptoms of glaucoma; the left lid droops a little, and there is slight recession of the ball. The author thought that the operation might take the place of iridectomy if done in time, the relief given by eserine appeared a favorable indication for the operation.

Dr. PARKHILL of Denver reviewed the history and technique of the operation, and advocated incision anterior to the sternocleidoid, instead of posterior; this avoided injury to the spinal accessory nerve, the operation in Dr. Block's case had been by anterior incision.

Pancreatitis.—Dr. LEONARD FREEMAN of Denver reported a case of "acute traumatic pancreatitis", the patient died after operation.

Dr. PFEIFER of Denver reported a case of sudden death from this cause; for the first six hours after the patient's fall from a wheel the injury did not cause alarm, and the condition was not clear until the autopsy was done.

Operation for Cancer of the Breast.—Dr. C. A. POWERS of Denver presented a paper on methods and results in operation for cancer of the breast. He said that the word "complete," as applied to making the operation radical, and also the length of time allowed before claiming a cure, were constantly being extended; the accepted three years of immunity was only relative as a test; he recommended the Warren flaps to cover the wound.

Examination of the Fæces.—Dr. C. D. SPIVAK of Denver read a paper on diagnostic value of macroscopic examination of the fæces, and showed a bucket which he had devised with a fine wire-mesh top and bottom for this purpose. Foreign substances, undigested particles, mucus, etc., could in this way be easily washed out and collected.

Pneumonia.—Dr. J. N. HALL of Denver reported seventy cases of acute lobar pneumonia. He thought the disease more frequent than formerly, owing to more persons arriving at advanced years. It was very frequent in the homes and hospitals of Colorado; he found crises in twenty-six cases; the complications were tuberculosis in seven, typhoid fever in three, empyema in five, albuminuria in eight.

Dr. R. H. REED of Rock Springs, Wyoming, had noticed that cases of pneumonia in which there was considerable expectoration of blood did well, and thought this suggested the value of venesection; he thought the altitude of the Rocky Mountain region rendered pneumonia more grave than at sea level.

Aseptic Surgery.—Dr. R. H. REED then read a paper on the "Chemical Treatment of Trauma," in which he laid much stress on the preparation of catgut for sutures and ligatures.

Dr. J. S. PERKINS of New Mexico read a paper on "How to Do Clean Surgery at Small Cost." He said it could be done at the patient's home with instruments and sterilizing appliances, carried in a satchel or improvised on the spot. It was not necessary to move pictures or to take up carpets. It was sufficient to spread an aseptic sheet on the floor and stretch and suspend one over the table.

The Appendix.—Dr. E. P. HERSHEY created something of a sensation, and raised a storm of protest by a paper on the "Function of the Appendix." He had noticed that patients with appendicitis previously suffered from constipation and did so also after operation, and he thought the organ secreted mucus, the discharge of which aided in keeping liquid the fæces in the cæcum. After operation, patients had discomfort in the iliac region, wrongly attributed to adhesions, which was relieved by a purge. The organ had a valve and sphincter, and was naturally placed and directed to perform the function claimed; it was not a vestigial organ.

Tachypnœa.—Dr. J. T. ESKRIDGE of Denver presented a paper on a case of rapid respiration (143 per minute) in fatal organic disease of the brain. The respiration was much more rapid when the patient was asleep, the maximum of rapidity being reached then. The cause was irritation of the pneumogastric. The case was obscure, and difficult to diagnose from hysteria but for the rapid respiration and absence of adequate relationship between that and the pulse and temperature.

Mountain Fever.—Dr. W. W. WADING of Mt. Pleasant, Utah, read a paper on mountain fever, and claimed that it was a distinct type of fever, and not a mild typhoid, as heretofore supposed; the symptoms were headache, backache, rigor, and then fever of 103°, constipation, brown-coated tongue, no hemorrhage nor delirium. The duration was from twelve to twenty days, and the mortality only five per cent.

Dr. PHILLIPS of Rocky Ford, Colorado, thought this fever was a modified typhoid.

Conservative Gynecology.—Dr. W. W. GRANT of Denver

entered a plea for "Conservative Surgery of the Ovaries and Tubes." He related a case of his in which the diseased ovary was removed, and the other, being cystic, was opened and a portion only removed; the menses promptly returned, and were normal for two years, when pregnancy occurred.

Gastrectomy.—Dr. E. S. WRIGHT of Salt Lake City reported a case of removal of the stomach for cancer; the tissues were so diseased that it was impossible to make an anastomosis between the duodenum and œsophagus, and he had to make a duodenal fistula; the patient died the next day.

Address of the President.—The address of Dr. C. K. FLEMING, the retiring President, was a masterly plea for the institution of a national medical bureau and high and uniform standards in medical education and requirements for registration. He regarded State legislation in attaining these ends as almost hopeless. A vote of thanks was tendered for the address.

Dr. R. Harvey Reed of Wyoming was elected President, and the meeting closed with a banquet at the Brown Palace Hotel. The next meeting will be at Cheyenne, Wyo.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 21, 1901.

	Cases.	Deaths.
Measles	50	1
Diphtheria and croup	155	29
Scarlet fever	65	2
Smallpox	3	1
Chickenpox	5	..
Tuberculosis	283	159
Typhoid fever	122	21
Cerebro-spinal meningitis	..	3

Schools of Tropical Medicine in Great Britain.—In *Janus* Dr. Davidson of Edinburgh gives a sketch of the schools of tropical medicine in Great Britain. First in the list to pay any attention to this study comes Edinburgh University. Lectures on the subject were commenced there in 1886 by Dr. Felkin, and continued by him up to 1898, when Dr. Davidson took his place. The University of Edinburgh established a Lectureship in Diseases of Tropical Climates in February, 1899, and provided for a concurrent course of practical instruction in the parasitology and bacteriology of tropical diseases, conducted by Dr. Greenfield, the professor of pathology in the university. The London School of Tropical Medicine was founded in 1899. Dr. Manson was the originator and is the presiding genius of the institution. The school was founded "not only to acquaint the student with the diseases of the tropics, not only to teach him how to treat the various ailments he may meet with, but also to put him in the way of investigating tropical diseases." In carrying out these aims, apart from the hospital, which affords abundant material for clinical instruction, laboratories, a museum and a library have been provided. There are no fewer than nine lecturers in connection with the school, each taking up the subjects with which he is most conversant. There are three sessions yearly, and the average number of students has been about twenty-four. The Liverpool School of Tropical Medicine was also started in 1899, in connection with the University College and the Royal Southern Hospital. Young as it is, it has a history of which it may well be proud. It is now arranging for its seventh research expedition. These scientific expeditions of trained men, furnished with the latest instruments and apparatus for the investigation of particular diseases on the spot, is the conception and special feature of this school. The work of the school is directed by Major Ross. He is assisted by Drs. Ould, Balfour, Stewart, and Grünbaum. During the year 1900 over twenty students attended the school. The University of Aberdeen has a lectureship on tropical diseases, founded in 1899, on pretty much the same lines as those which obtain in Edinburgh. So far as the number of students goes, Aberdeen takes the first position among the schools of tropical medicine in Great Britain; no fewer than sixty-seven having attended the course during the past three years.

Influence of Formic Aldehyde upon the Metabolism of Children.—Tunnicliffe and Rosenheim, writing upon the above subject in the *Journal of Hygiene*, draw the following conclusions: 1. In healthy children formic aldehyde, administered with the food in doses up to 1: 5,000 in milk, or 1: 9,000 in total food and drink, exerted no appreciable effect on the nitrogen or phosphorus metabolism or fat assimilation. The analytical figures suggest, however, that formic aldehyde has a tendency to diminish phosphorus and fat assimilation, and hence it may be inferred that in larger doses, or if continued for a longer period, it would act in this direction. This effect is referable to an influence upon pancreatic digestion. 2. In healthy children formic aldehyde, in the above doses, produces a retention of water in the body. 3. In a delicate child, formic aldehyde in the above maximum dose, had a clinically measurable deleterious effect upon the nitrogen, phosphorus, and fat assimilation, again referable to an action upon the pancreatic digestion, combined with a slight intestinal irritant action. There was a slight tendency to stimulate the katabolism of proteid material. 4. In a delicate child, formic aldehyde increased the volume of urine and the weight of fæces. 5. In all cases, the excretion of lecithin in the fæces was diminished under the influence of formic aldehyde. This effect is probably referable to a stimulating action of formic aldehyde on the lecithin-splitting ferment of the pancreas. 6. In no instance did formic aldehyde exert any appreciable intestinal antiseptic action. 7. In no instance was there an influence on the general health or well-being of the child.

Treatment of Whooping Cough.—Dr. Thomas Ganggier, writes the Swiss correspondent of the *Lancet*, has issued a résumé of upward of one hundred cases, treated principally by preparations of quinine, which in the later cases was combined with hydrotherapeutic measures. The cases referred to were in children under six years of age, the three youngest being two, five, and eight weeks respectively. There was no fatal case observed, though five cases came under treatment with single pneumonia, sometimes of a very severe type. The number of paroxysms of whooping cough never exceeded thirty-two in twenty-four hours, and they decreased rapidly during the second week of treatment. The general state of health on discharge, generally after two, three, or four weeks of treatment, was often so good that a change of air seemed unnecessary. Tannate of quinine proved of little effect. The best results were obtained from hydrochlorate of quinine dissolved in water, and administered in milk in doses of from one to three grains three times a day before meals, according to age of patient. Very good results were also obtained from the use of euchinin, in the form of a powder, which has the advantage of being almost tasteless, and can more readily be given to children. The dose varied from two to six grains two or three times a day before meals. Wet packs, reaching from armpits to ankles, had a very soothing effect, when properly applied and well covered with flannel. They were left on for two or three hours or for the whole night, and in case of concomitant fever could be renewed several times in the twenty-four hours.

The Decline of Beriberi in the Japanese Navy.—A Japanese journal of recent date gives the following

account of the practical extermination of beriberi in the Japanese navy by suitable feeding. Nothing is more remarkable than the record relating to beriberi, which used at one time to be such a scourge in the navy. Thus, in 1883, the last year of the old system of diet, there were 1,230 cases out of a total force of 5,340 men, being a ratio of 231 cases per 1,000 of force, and the deaths were 40. In 1898, the total number of cases was 16 out of a force of 18,426, being a ratio of 0.87 per 1,000 and the number of deaths was 1. In fact, by a judicious system of diet, beriberi may be said to have been driven out of the navy altogether. The daily food of a man in the Japanese navy is now approximately, ½ lb. of bread, ⅔ lb. of meat, ⅔ lb. of rice, 5/16 lb. of vegetables, together with small quantities of preserved meat and fish, fresh fish, cracked wheat, beans, flour, tea, sugar, roasted barley, soy, etc. When members of a mess consist of more than five, the value of one man's rations in money for every five members is given to the mess, and with it the men buy any food they like. Not less remarkable is the steady increase of body weight that has taken place since 1884, when the improved system of diet began to be operative. The average weight in that year was 121 lbs., approximately, and it henceforth increased regularly year by year, until in 1898 the figure was 130 lbs.

The Sale of Secret Medicines not Allowed in Austria.—Carl Bailey Hurst, United States Consul-General in Vienna, reports to the State Department that the sale of secret remedies has always been strictly forbidden in that country. Trade in such medicines and advertisements of the same are under strict surveillance of the law. Further, those medical preparations of which the prescriptions are not open to inspection by physicians, or in the prescription of which the substance of the medicinal ingredients cannot be definitely recognized as to kind and quantity, may not be kept for sale by apothecaries. Only those manufactures may be considered as pharmaceutical specialties that contain drugs acknowledged to be medicinal remedies. Every new medicinal preparation intended for use by the public must be reported to the authorities, and its sale may not be begun until such authorities have found no reason to prohibit the same. Prescriptions of foreign medicines must be accompanied by precise directions for their preparation from the foreign manufacturer, and be provided with his signature and business stamp. The regulations in Austria in regard to the advertisement of patent medicines are also strict. All laudatory notices in local publications of cures and remedies coming from abroad constitute a transgression of the trade laws, and under certain circumstances afford a foundation for complaint of unlicensed medical practice.

A Victory for the Ohio State Board of Medical Registration. The Ohio State Board of Medical Registration and Examination has obtained from the Supreme Court of Ohio an important decision which establishes its right to determine whether a medical college is in good standing. The board threw out the diplomas of the Hygeia Medical College of Cincinnati, whereupon the college applied for a writ of mandamus compelling such recognition. The court sustained the board, the decision in effect being that a writ of mandamus will not issue, on the relation of a medical college, to compel the State Board of Medical Registration and Examination to recognize the college as a medical institution in good standing, or to compel the board to issue certificates to practise medicine in that State to holders of diplomas from such college. This decision will establish the Ohio board on a firm foundation, and the precedent thus created will strengthen the hands of boards in other States.—*Buffalo Medical Journal.*

Are Röntgen Rays Infallible?—A number of papers have recently been written concerning the fallacies and difficulties in the diagnosis of fractures by means of the Röntgen ray. A case has recently come under our notice which illustrates forcibly the difficulty in localizing foreign bodies in the alimentary canal below the œsophagus. A patient swallowed a dental plate, made of gold, with two teeth attached. When he was admitted to the hospital, the plate had passed the cardiac orifice of the stomach. For three consecutive days, an expert radiographer, manipulating the most up-to-date apparatus, failed with either fluoroscope or sensitive plate to demonstrate the presence of the denture, and this notwithstanding the fact that buttons, coins, and other objects could be distinctly seen through the whole thickness of the body. The peristaltic movements of the intestines would account for the failure, in the case of the photographic plate, but it is difficult to understand how these movements would interfere with the view obtained by means of the screen.—*The Medical Press.*

Hæmophilia Neonatorum.—J. G. Wm. Greef believes that the nature and etiology of hæmophilia are yet unknown, none of the theories so far advanced account for all cases, and all of them are open to some objections, the chief one being that they are incapable of proof. Autopsy shows no characteristic nor constant lesions. He presents three cases in which there was no history of heredity. The only condition apt to be confused with hæmophilia is melena neonatorum, the diagnostic point being the discharge of blood from the gastro-intestinal tract in the latter disease. The author inclines to the belief that hæmophilia is due to abnormal permeability of the vascular walls. The rational treatment in cases surviving the first attack consists of measures to harden the body, improve nutrition, and avoid external injury.—*Pediatrics.*

The Diazo-Reaction in Typhoid Fever.—M. E. Sacquépée has found by experimental research that the diazoreaction, which is nearly constant in typhoid fever, appears, as a rule, a few days before the hyperpyrexia, its curve being almost parallel (except for duration) with the thermal curve. If it disappear gradually and definitely, we may predict the near approach of a fall of temperature, unless complications should arise. It may disappear early and suddenly without clouding the prognosis, but should it persist after a fall in temperature, we should be on the watch for complications or for coexistent disease, such as peritonitis or tuberculosis.—*Archives Générales de Médecine.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended September 21, 1901:

THE USE AND LIMITATIONS OF THE ELASTIC LIGATURE IN INTESTINAL SURGERY.*

BY THEODORE A. McGRAW, M.D.,
DETROIT, MICH.

IF we study the literature of intestinal anastomosis we shall find that of the numberless methods devised for its production, only two have thus far continued in favor with the profession. A surgeon who has no method of his own devising will almost invariably resort either to incision and suture or to the Murphy button. Both of these methods of operating, however, have defects which, every now and then, lead to disaster and death. In both, the cuts in the intestine cause more or less hemorrhage when even a slight loss of blood is illy borne by many of the anæmic patients upon whom we have to operate. In both there is danger of infection arising from the escape of intestinal contents from the opened bowels. In both there have at times been failures in union, and deaths from general peritonitis.

Incision and suture, if carefully done, take a great deal of time—a fault which, in very exhausted patients, may make the difference between life and death. The Murphy button can be more speedily applied than the suture, but it has some disadvantages which the suture has not. In the first place, the size of the opening must be limited to that of the button, a very decided disadvantage when a large permanent fistula is indicated. Then its lumen may be occluded by seeds or fecal concretions. When the bowel below a chronic obstruction has become, as I have often seen it, small, thin, and contracted, it is sometimes extremely difficult to get a button in at all without tearing the bowel. In some cases the button has remained permanently in the stomach or duodenum. In all, it is a large foreign body which must find its way through a long, small intestine with a possibility of causing irritation or obstruction.

It is because these methods are not in all respects satisfactory, that I wish to urge again upon the profession the use in certain classes of cases of the elastic ligature. I first introduced this method of making an anastomosis in a paper read before the American Medical Association in May, 1891. I shortly afterward became acquainted with the Murphy button, and abandoned my own method in its favor. The chief reason which actuated me in giving it up then, and which now makes surgeons reluctant to adopt the method by the ligature, is, I am now convinced, founded upon a false pathology.

It seemed to me then that a method which made an immediate communication between the two viscera and permitted without any delay the passage of food must be superior to one in which the opening was delayed for three or four days. I assumed that such patients could immediately get some nutriment into the bowel through the new channel. I left entirely out of my reckoning those pathological conditions which interfere with the motility and function of a bowel for many hours, or even days, after it has been injured. Long years of observation of patients after laparotomies have brought me to the conclusion that in most cases the stomach and intestines are not able to avail themselves of the new channel until after the lapse of two or three days, even when the course of the wound is perfectly aseptic.

The anæsthetic produces in most patients a gastric irritability, which lasts many hours. Besides that, the injury done by the operation itself inhibits for an indefinite time the muscular contractions of the gut and with it the digestion and absorption of food. Even the troublesome vomiting after laparotomies may not be due to any gastric activity, for there is reason to believe that the diaphragm and abdominal muscles are the only ones concerned in its production.

Only in this way can we explain the vomiting which occurs sometimes when a "vicious circle" has formed after a gastroenterostomy; for, if the muscles of the stomach were acting upon the newly formed fistula, they would draw its edges apart and thus empty the contents of the stomach into the intestine, whereas a convulsive movement of the diaphragm and muscles of the abdomen forces them out through the œsophagus. It is a well-known physiological fact, too, that dogs in which the stomach has been removed and a bladder inserted in its stead can nevertheless be made to vomit by stimulating those muscles into activity. It is rarely the case that gas begins to roll in the bowels before the end of the second day, and often the period of absolute quiescence lasts four or five days. We may safely assume that during this period all physiological processes concerned in the digestion of food are partially, if not completely, suspended. For this reason the belief is a delusion that an immediate anastomosis has any advantages over one which ensues three or four days after the operation. Indeed, where the stomach is the subject of operation it is highly probable that more nutriment will be absorbed from high enemata than from any food which can be introduced into the upper bowels.

Besides this theoretical objection which some surgeons have to the use of the elastic ligature, others are deterred by the feeling, expressed to me by a distinguished surgeon, as follows: "I like to see the opening into the bowels myself." There is a fear that the ligature will not certainly accomplish its work. This fear is absolutely without foundation if the operation is properly performed. In a large number of operations on dogs, in which the intestine is much thicker than in man, I have never yet met with a failure. Now, while the supposed disadvantages of the ligature are illusory, its advantages are very positive and definite. It is the quickest of all operations for the production of intestinal anastomosis.

A few Lembert stitches, the passage of the ligature

*Read at the twenty-seventh annual meeting of the Mississippi Valley Medical Association, at Put-in-Bay, O., September 12–14, 1901.

through the adjacent viscera, the tying of a knot, a few more Lembert stitches, and the operation on the intestine is completed. There is no incision of the bowel, no loss of blood, no escape of fæces, and no exposure to peritoneal infection from the bowel contents. The operation is followed by a minimum of shock and pain, and at the end of three or four days there is an anastomosis with a union by first intention. The bowel does not slough under the ligature, but undergoes a process of absorption, and when examined at the end of three or four days the edges of the orifices are found closely united without any raw surface whatever. There is, too, the enormous advantage of this method over the button, that the surgeon can govern exactly the length of the opening and make it large or small as may seem best.

Simple as this operation is, its success will, nevertheless, depend upon the observance of certain positive rules in its application. First of all is the choice of a proper instrument. This must be a firm, hard, round rubber cord, at least two millimeters in diameter. This must be made of the very best quality of rubber. It will not do to substitute for this a rubber thread or a flat band. Nelson Baker & Company of Detroit have recently had molds manufactured for the production of ligatures which taper at the end. This facilitates the insertion of the cord in the needle and enables the surgeon to draw it through a very small aperture without injuring the tissues.

The bowels to be connected must be brought in apposition and fastened together with a row of Lembert stitches. The cord must be then passed through first one and then the other bowel always in the direction of the longitudinal axis, and drawn tightly together in a single knot. This knot is securely fastened by means of a stout silk thread, which is tied firmly around it. As the thread is tied while the rubber is on the stretch, it cannot slip off the ends of the rubber when the latter is relaxed. The ends of the rubber are cut short. An additional row of Lembert sutures buries it from sight, and the intestines are returned into the abdomen.

Now the cases in which this method is adapted are, first, all gastroenterostomies. After meeting with two cases in succession of so-called "vicious circle" after gastroenterostomy, in which the food passing through the artificial opening has persistently found its way into the duodenum instead of into the distal limb of the jejunum, I have come to the conclusion that Roux's method of combining with every gastroenterostomy an enteroenterostomy between the two limbs of the jejunum is the only safe method. If this is done by incision and suture the surgeon has to make four incisions into the bowels and make two difficult sutures. An operation by this method takes a great deal of time and is exceedingly exhausting. If, on the other hand, the surgeon operates with the Murphy button he may accomplish the purpose quicker, but makes, nevertheless, the four incisions and leaves two large foreign bodies in the intestines. This more than doubles the danger which would arise from a single anastomosis, as the wound of the enteroenterostomy has not only to get rid of its own button, but must also suffer the passage through it of the button used in the gastroenterostomy. The superiority of the elastic ligature over all other methods when an enteroenterostomy is added to a gastroenterostomy cannot be doubted by anyone who has used the procedure. The quickness of its application, its freedom from danger, of sepsis, and absence of all complications are in brilliant contrast to the defects of other methods. Wherever a gastroenterostomy is required, the method is the best available provided the surgeon does not wish to open the stomach. Even then it may seem best adapted to existing conditions. Thus Dr. Mixter, in a case of an ulcer of the stomach in which relief had been obtained by means of a gastroenterostomy with a Murphy button, was obliged to operate a second time on account of the recurrence of pain and gastric irritation. On opening the stomach he found that the artificial opening had very nearly closed. He passed the elastic ligature through the same opening, closed the wound, and the patient recovered.

In gastroenterostomy for chronic ulcer the objection which some surgeons feel toward the method on account of the delay in completing the anastomosis would have no weight. The open pylorus would permit the free passage of the ingesta as soon as the stomach had recovered its motility. In chronic ulcer, therefore, the question is not one of nutrition, but of relief from the irritation caused by the long contact of food, by the friction produced by the churning of the food in the stomach and by the corroding effect of the acid, whose secretion is excited by the presence of the ingesta. The object of the operation, therefore, is to secure a quick evacuation of the stomach by making a new and free outlet for everything taken in. In stenosis of the duodenum, intestinal anastomoses, according to Kelling, are contraindicated, for the reason that the presence of food in the duodenum inhibits the contraction of the gastric muscles. If, therefore, there should exist a stenosis of the duodenum at its junction with the jejunum and an anastomosis were to be made between the first division of the duodenum and the jejunum, the operation would fail to give relief. More or less of the food would pass into the duodenum beyond the anastomosis and fill it up. The stomach would no longer empty itself, and the obstruction therefore would continue. If in stenosis of the duodenum, therefore, the surgeon ventures upon the operation for anastomosis at all he should make the junction as near as possible to the strictured portion, in order not to leave a blind end in the duodenum, which, filled with ingesta, would exercise this inhibiting influence on the stomach motility. It is better in these cases to relieve the obstruction by operations directly upon it.

In partial stenosis of the small intestines, other than the duodenum, we have conditions especially adapted to operation by the elastic ligature. In these cases, as a rule, the distress caused by the narrowing of the intestine does not interfere as seriously with the general nutrition as does a pyloric stenosis. When the ingesta are forced through the narrow opening there is usually terrific pain, but the food passes on nevertheless and is absorbed. For a day or two before operating on these cases purgatives should be given and all food withheld from the stomach. Nutrition may be kept up by nutritive enemata. If the obstruction is caused by cicatricial contraction, the needle and ligature may be passed into the intestine an inch or more from the point of obstruction and carried through the existing channel and out again through the other limb of the bowel. The ligature then doubles the gut upon itself, and when it cuts through leaves an ample channel. Inoperable tumors of the gut demand the elimination of the diseased portion of the intestine from use by an anastomosis of the healthy bowel above and below the diseased point before obstruction has taken place. The elastic ligature is then the very best instrument for its production. It may also be used when the obstruction is only partial. In complete obstructions, from any cause whatever, which require an incision into the bowel for the evacuation

of gas and fæces, the anastomosis should be made by other methods.

Radical operations for the removal of cancers of the large intestine are exceedingly dangerous. Even when determined on, however, they may be advantageously preceded by the formation of an anastomosis.

In so doing the ligature should be passed through one of the longitudinal bands where the bowel is thickest. All operations of this kind are rendered more uncertain on the colon than on the small intestine by reason of the greater solidity of the fæces. Lines of suture which will hold fast against any amount of liquid or semi-liquid substances may be torn apart if subjected to the pressure and friction of more solid masses. Kelling, in his experiments on sutures of the stomach, found them safe to resist the pressure of large amounts of fluid, but easily ruptured by hard ingesta. For this reason it is well in any operations on the large intestines to strengthen the line of union as much as possible by double or triple lines of Lembert sutures, and by wrapping the omentum around the wounded gut and securing it in place. The serous membrane, too, should be scratched in order to make its adhesion more certain. I have said that complete obstruction of the bowel cannot be treated to advantage by the elastic suture. There is, however, an exception to this rule in those cases of acute obstruction in which the bowel has become gangrenous and in which excision of the mortified segment with subsequent junction of the ends of the gut seems inadvisable.

Extreme exhaustion of the patient is the cause, in most of these cases, which compels the surgeon to postpone the radical operation and to content himself with providing for the sloughing gut by fastening it outside of the abdominal wall. There may be also another reason for deferring excision when there is some uncertainty as to whether the bowel is actually gangrenous, or, if so, as to the possible extent of the gangrene. Cases of this kind occur in strangulated hernia, in occlusion from bands of organized lymph, in volvulus and in intussusception. A good rule would be, in the treatment of these cases, where the strength of the patient is good and when the line of demarcation is sharply defined at once to amputate the dead portion and to join the severed ends of the intestine with a Murphy button or by suture. When, however, the patient is on the verge of collapse, or when it is uncertain whether the coil of intestine is beyond recovery, or when there is no distinct line of demarcation to guide the surgeon to the proper point where an excision may be safely done, then another mode of procedure which will offer the patient a better hope of life is to be preferred. An anastomosis may be made by the elastic ligature in an evidently healthy part of the intestine. The abdominal cavity may be protected, as far as possible, from contamination by a packing of iodoform gauze, and the dead portion of the gut removed. The ends of the cut intestine, or the suspected coil, if its death is not certain, should be sutured to the abdominal wound. If a patient thus treated should happily recover, the progress of the case would be somewhat as follows: The exposed portion of bowel would recover either without or with sloughing. If it did not die it could be gradually forced back into the abdominal cavity. If a fecal fistula formed, the fæces would for a time pass out of the open end of the upper segment. The orifice of communication made by the ligature would, however, gradually become the main channel for the discharge of intestinal contents.

The cicatrization of the wound would tend to close the cut ends of the bowel and eventually lead to healing. If, however, they should not close, the wound could in time be reopened and the simple operation of inverting and suturing the ends of the discharging bowel would be all that is required to bring the case to a happy conclusion.

THE PROPER METHOD OF TEACHING THE ANATOMY OF THE NERVOUS SYSTEM

BY L. HARRISON METTLER, A.M., M.D.,
CHICAGO,
PROFESSOR OF PHYSIOLOGY OF THE NERVOUS SYSTEM IN THE POST-GRADUATE SCHOOL OF MEDICINE OF THE STATE UNIVERSITY OF ILLINOIS, LECTURER ON DISEASES OF NERVOUS AND MENTAL DISEASES IN THE CHICAGO CLINICAL SCHOOL.

At one time anatomy and physiology were taught from the same chair. The interdependence of structure and function made this arrangement an eminently practical one, while the paucity of positive physiological data made it an equally convenient one. The knowledge of organic structures became so vast, however, in comparison with the knowledge of their physiological functions that the latter soon sank into a position of relative unimportance. The supremacy of anatomy was further emphasized by having added to it the related sciences of biology, histology, and embryology, and the art of surgery. All of this proved ultimately of the greatest advantage to physiology. The latter was soon divorced from anatomy, and at once began to make rapid strides as a distinct science. The pre-eminence of Albrecht von Haller, the "Father of Physiology," is a suggestive commentary upon the insignificance of physiology prior to his day, and its sudden rise and growth after it. So long as physiological data were merely inferred from anatomical appearances, it was inevitable that the study of the functions of living beings should remain an inferior science. The moment it was recognized that mere histological structure afforded no safe ground whereon to base physiological generalizations, but that the latter were to be formulated only after a large accumulation of facts obtained from direct observation and experimentation, physiology assumed its proper place as a science. Since that moment its advancement has gone on so steadily and rapidly that to-day it is guiding us to a better understanding of anatomical structure. This is true especially in regard to the nervous system. Spinal tracts and cerebral localizations would never have been known probably had it not been for pathologico-physiological observation and experimentation. It looks as though physiology were at last beginning to retaliate upon anatomy for its long, early period of subordination.

It is an unfortunate fact that the structure and arrangement of the central nervous system are still too widely taught as a part of general anatomy, aside from its developmental and functional relationships. I fancy it would be better in some respects if the consideration of the nervous system were omitted entirely from the works upon anatomy, and confined to those upon biology, embryology, and physiology; for not only are the old nomenclatures and arbitrary divisions false and misleading, but the discussion of it, apart from its development and function, tends to produce in the minds of the students a more or less arbitrary and confused picture of its architecture. The whole nervous apparatus is a most complex, compound organ, and much of what the student learns about it from most of the modern anatomies even has to be largely unlearned or rearranged in his mind when he comes to study minutely its functions. Let me illustrate.

The spinal cord, as it is usually taught anatomically, is a more or less independent organ, made up of certain columns of white matter and certain central

masses of gray. To these columns are attributed particular functions and assigned particular names and boundaries. Arbitrary divisions and subdivisions are laid, as, for instance, between the so-called anterior and lateral root-zones; fissures are described where there are no fissures; and mere disconnected, short, associative tracts are dignified with the name of column. As a result of all this, the cord in its entirety assumes, in a hazy way in the mind of the student, the characteristics of an individual, distinct organ attached somehow at one end to the brain, and giving off and receiving along its sides motor and sensory nerve roots. When the student comes to study minutely the physiology of this organ, he is amazed to find that he has to learn its structure from an entirely different standpoint, and that its physiological dissection seems to nullify many of the arbitrary divisions and arrangements made in it by anatomy. He discovers that it is far from being a distinct organ, separate from and subordinate to the brain, but that both it and the brain, together with the peripheral nerves, make up a composite organ whose parts overlap and run into each other in a most marvelous complexity of structure and function. He is surprised to learn that the term column is as applicable to the cellular gray matter as it is to the fibrous white matter, being, in fact, a poor term to be applied to either. He is not a little confused when he observes that the nerves are not given off and received by the cord, but that certain efferent processes are sent forth from its central ganglionic masses to terminate in the muscles, while the sensory processes from certain peripheral cells are merely received into it to arborize around its own cells. A series of ganglia, with their appropriate efferent processes, in and about which terminate certain afferent processes from without, constitute the cerebrospinal organ in the truest sense of the word. The peripheral neurons and the central neurons find merely a meeting place in the ganglionic gray matter surrounding the central canal, including the ventricles of the brain and the central canal of the cord.

For the sake of illustrating still further the difference between the anatomical and the physiological methods of studying the nervous system, and to emphasize especially the advantage of the latter when it is combined with the morphological and developmental methods, let me consider more in detail the structure, growth, and function of the spinal cord of the anatomists.

As everybody knows, the earliest appearance of a nervous system in the animal world is in the cœlenterates, namely, in the medusæ or jelly-fish. Among the polyps, just below the medusæ, and, of course, among the organisms still lower in the scale of life, the Protozoa, science has thus far failed to reveal any differentiated protoplasm which, by any stretch of the imagination, can be likened to a nervous system. It is not impossible, however, that future means of research may disclose still more primitive nervous systems than are to be found in the medusæ, for in the sea-anemones just below them, and even in the infusoria, there is a high degree of sensibility and purposive movement that is most suggestive of the presence of a highly specialized, reflex-acting neuromuscular apparatus. The whole class of Acalephæ, including the medusæ, are creatures so finely organized that they have a circulatory system, a neuromuscular apparatus, and digestive and generative organs. Their relation to the sea-anemones is made manifest by the fact that the young differ so widely from the adults that they assume forms resembling those of the hydroform polyps, and remain attached by their base to rocks, etc. In the jelly-fish certain primitive ganglionic masses, which, of course, are the mere differentiations of the primitive homogeneous protoplasm, one of whose qualities is that of irritability, are found scattered around and near the circumference of the umbrella-like body of the animal. From these ganglionic masses processes extend across the body in various definite directions, and down into the tentacles suspended beneath and encircling the mouth. It may be fanciful, but is not altogether irrational, to suggest that this series of ganglia surrounding the opening of the gastric organ represents the differentiated protoplasm surrounding the primitive mouths of the infusoria, or fixed points at which some of the unicellular protozoa, the astomata, take in their nutriment. As Professor Huxley observed, the Protozoa are unicellular organisms, whose essential characteristics may all be predicated of the ova of any of the animals higher in the scale of life, but even as unicellular organisms, the simplest individuals of them are far more complex than is implied in the use of the adjective unicellular. Nevertheless, unicellular organisms do not seem to possess a special nervous system. As they are complete units in themselves, all their parts functionate harmoniously together in the digestive, generative, and circulatory processes, and in the exhibition of motion and sensation. Like them, the individual units that go to make up the multicellular organisms, as Metazoa, manifest the same completeness and independence of function. Daughter-cells carry off from the parent cell the same general structure and functional potentiality that belong to the latter. In a community of organisms, such as the cestoid worms, each segment, though a highly organized creature and a member of a community, has the same structure and potentiality as every other segment. Now, if the union of such a community of independent organisms were to become so close that a differentiation of function, resulting in a division of labor for the greater advantage of the entire community, could be developed, and the whole community become a highly complex animal, the latter, in its development and structure, would nevertheless reveal the characteristics of the individual units of which it is composed. When we say that this is observable in the life history of the higher animals only during their earliest period of embryological development, we are enunciating the great law first propounded by Fritz Müller, and afterward called by Haeckel "the biogenetic fundamental law," namely, that every animal in its growth, from the egg to the adult, passes through a series of stages which recall the stages through which its ancestors have passed in the historical development of the species from a primitive form. The Metazoa, in a word, are nothing but unicellular communities in which particular members or groups of members have relinquished some functions so as to be able to specialize more keenly in regard to others. Segmentation is the rule, developmentally and potentially, throughout the entire animal world. Wholes are made up of parts, which parts are more or less complete within themselves, because phylogenetically these parts have all been capable at one time of a separate and independent existence. The way in which the Actinozoa grow up into compound masses of associated zooids, by means of gemmation and fission, causes them to stand in the same relation to the Actinia that the compound Hydrozoa do to the Hydra. Of the Hydrozoa the Hydra is the type, just as the Actinia is the type of the Actinozoa. As in the Hydrozoa, the Actinia is composed essentially of two layers, namely, the superficial polygonal-celled layers, and the deep dermal layer in which are found the superficial circular and deep longitudinal

sets of muscular fibers. The whole group of Polyps, and especially the Hydra, manifest marvelous actions, sensations, and functional powers that are not unlike those of more highly ranked animals. And yet, curious and familiar is the fact that these low creatures may be cut into segments and otherwise mutilated, when each severed and mutilated part will begin to grow and assume the rôle of a new and perfect individual.

Multicellular organisms being, therefore, more or less segmental in structure, each segment, so far as it is independent of all the other segments, will exhibit an independence of structure and function. In the higher types of the Metazoa, wherein adaptation to environment has wrought, through natural selection and other forces, a closer union between the component segments and a higher degree of functional differentiation, the structural and functional independence of the segments appear less obvious. Being sharply differentiated in function, they are all the more closely bound to and made dependent upon those segments whose functional activities make up for their deficiencies. The immense variety of form, in all classes of animals below the Articulates, obscures to a certain extent their segmental structure. The star-fish and the sea-anemone are as much segmental creatures as are the worms and insects, though their forms would lead one to think superficially otherwise. The Acalephæ (sea-nettles and jelly-fish) are cœlenterates close to the Actiniadæ, while on the other hand, the Echinodermata, which so closely resemble the cœlenterates, are regarded as mere aberrant groups of Annuloida, which, with the Arthropoda, constitute Huxley's class of Annulosa, or Articulata. In the star-fish, as in the jelly-fish, the segmental ganglionic nervous center encircles the creature's mouth, while the processes extend into the arms or rays. When these rays coil up so as to approach one another, and touch along their edges, the form of the creature is changed into that of the ball-like sea-urchin with the nervous apparatus still relatively unchanged. The central ganglia still surround the opening of the alimentary cavity, and send their processes into the peripheral parts of the globular creature. Many of the radiates, as, for instance, some of the Holothuriidæ and Sipunculidæ approach the molluscs and worms in form and in other respects depart quite considerably from the rest of the Echinodermata. In a word, they become more distinctly articulated animals, which, as some one has said, are composed of a series of rings placed edge to edge. Each ring or segment, like the primitive creatures which we have just been studying, contains a ganglionic mass of nervous matter encircling an alimentary cavity, from which ganglionic mass proceed nerve tracts to the musculo-cutaneous and visceral structures of the corresponding segments.

If a row of these rings or segments, or metameres, are placed end to end, and are intimately united to one another, we will have an Articulate in which each metamere will have its central alimentary apparatus surrounded by a mass of ganglionic gray matter, connected by appropriate afferent and efferent processes to the musculo-cutaneous and visceral portions of the metamere. In this Articulate, a high degree of development will involve the closest sort of a union of all the metameres for the sake of coördination and harmony of action; consequently the alimentary organ will become a tube, extending through the entire length of the creature, with a tubular mass of gray matter more or less inclosing it throughout its length, while the processes to and from this tubular mass of gray matter will assume the appearance of a row of dorsal and ventral nerve-roots along its sides. New columns of short nerve tracts, consisting of neuraxons, extending for purposes of coördination into adjoining metameres, will lie close beside the tubular gray matter. Such a creature would obviously be capable of an exalted degree of coördinate, reflex action, and would be able to lead a fairly satisfactory and independent existence. Like the amphioxus, it would be endowed with only a spinal cord. It would be very low in the scale of life, but it would possess all the essential nervous characteristics of the higher Articulates. The later alterations that have taken place in this primitive picture of an Articulate are all of the non-essentials, and are, in fact, the results of adaptation to environment, working through the law of natural selection. When parts of the body and particular viscera undergo extraordinary development to fit the animal for its changed environment, the central gray masses of nervous matter undergo a parallel increase of development in the corresponding representative metameres. The development of the legs and arms, the increased activity of the circulatory and respiratory apparatus, the elaboration of the visual, auditory and other special sense organs, all provoke corresponding enlargements and complexity in the related parts of the central gray deposit. In this way the great nerves of the head have sprung from huge ganglia in the encephalon and cord. So great have been some of these external head changes that the terminations of some of the cranial nerves have been dragged into parts not represented strictly in the metameres from which the nerves themselves take their origin; hence the complexity and confusion that obtain among the cranial nerves. In spite of all these variations and complexities, however, the primitive articulate type of the central nervous system is distinctly traceable.

If there be any truth in the principle of evolution, the articulate arrangement just described ought to be discoverable in the structure of the vertebrate nervous system. Owen says a vertebrate is but a clothed sum of segments, and is therefore essentially an articulate. The segmental character of the bony spine is obvious enough. The segmental character of the cord is also clearly indicated in the series of pairs of spinal nerve-roots, each pair of roots emerging, as it were, from the sides of a disc, and each disc representing a primitive metamere. The spinal cord of the vertebrate may be regarded as a series of discs superimposed one upon the other, each disc containing a ring of ganglionic gray matter surrounding a central canal, which is patulous from the cerebral ventricles to the caudal extremity of the cerebro-spinal axis.

Here a startling question presents itself. Can it be possible that the cerebrospinal central canal represents the primitive alimentary canal of the lower forms of life? Yes. It is not only possible, but more than probable. If the central canal represents the remains of our primitive alimentary tube, we have at hand the best explanation of the presence of the ciliated epithelium, and other structures lining it, and of the histological structure of the cerebral hypophysis. Embryologically, physiologically, and pathologically, it is made clear that the infundibulum and pituitary body are the remains of the opening between the mouth and archenteron. As we observed in the cœlenterates, the most primitive ganglionic mass surrounding the primitive mouth, so here we discover the oldest part of the central nervous system encircling the forward part of the primitive alimentary tract. As this œsophageal brain of the lower forms of life began to enlarge in correspondence with the head changes, with the development of the cranial nerves, and with all the variations made necessary by the higher degree of general

organization, the alimentary tract became encroached upon and so narrowed that in some animals—scorpions, spiders, Pedipalpi—alimentation was reduced to the mere sucking of blood. Cephalization was overcrowding alimentation. Ultimately the primitive alimentary canal became completely occluded by the enlargement of the œsophageal brain, and the present vertebrate alimentary tract had to be evolved. The evolution of this tract forms a remarkable study, and its comprehension clears up much of the mystery and confusion overhanging the peculiar arrangement and course of some of the cranial nerves. This fact, among others, proves conclusively that the developmental and physiological method is the only one by which these nerves, as well as the whole nervous system, should be studied.

The fundamental, vertebrate cerebrospinal axis is thus seen to be a mere readaptation of the articulate organ, and through the latter, of the primitive segmental ganglionic nervous matter which first made its appearance distinctly in the cœlenterates. It is seen to consist essentially of a series of ganglionic rings surrounding the remains of the primitive archenteron, each ring of gray matter being connected by associative tracts (anterolateral and posterolateral root-zones), with the rings above and below it, and sending out and receiving efferent and afferent processes to the musculo-cutaneous and visceral surfaces related to the particular metameres in which the rings are found.

The spinal cord of the anatomists includes, however, more than what I have just described; but developmentally and physiologically it is composed of these elements, and of nothing more. The other columns of the cord, usually described as part of it by the anatomists, are the so-called long tracts that belong to the encephalon and to the posterior root ganglia. They are a part of the cord only by grace of position, and they terminate in it by means of arborizations within its gray matter. If these so-called long tracts are to be discussed with the cord, then the whole cerebrospinal apparatus (encephalon, cord, and posterior root-ganglia) must be considered in toto. In anencephalous monsters the pyramidal tracts are absent; while, on the other hand, the monster observed by Leonowa, in which the spinal cord was wanting, while the posterior spinal ganglia were present, proves the independence of the long sensory tracts. The pyramidal tracts, both crossed and uncrossed, are merely the downward projecting neuraxons of the cortical cells which make up the extreme frontal ganglionic mass of the entire cerebrospinal axis, and by means of whose terminal arborizations in and around the cellular gray matter of the ventral or motor areas of the various segmental ganglia of the cord, the cortex exercises an inhibitory control over the movements of the body. They form the voluntary motor paths, and vary much, both in size and location, with the phylogenetic and ontogenetic variations of the teachable cortex. The long sensory tracts, including the posteromedian and posterolateral, the direct cerebellar, the anterolateral ascending and descending, together with some other unnamed tracts, are all merely the projection inward and upward alongside of the primitive cord, of the processes of the cells found in the ganglia of the posterior roots. Some of these tracts are greatly broken and complicated, as, for instance, the tract of which the direct cerebellar and Clarke-Stilling columns constitute a part. The various afferent paths seem to have a most intimate connection by means of their terminal arborizations with the gray matter of the primitive cord. It is not improbable that this primitive gray matter exercises a high degree of functional activity in coördinating and rearranging all impouring sensations before transmitting them on to the centers of consciousness, where they may be psychically distinguished and interpreted.

By the older physiologists, the spinal cord was described as an organ, just as they would describe the heart or liver, whose functions were the conduction of impulses between the brain and the nerves, the elaboration of certain reflex, automatic, and coördinating phenomena, and the maintenance of the tone and nutrition of the muscles. As an outcome of the newer conception of the nervous system (a conception due in part to the neuron theory), both the structure and function of the cord have been much simplified. It is recognized that the primitive segmental character belongs essentially to the entire cerebrospinal axis; and that the real, ultimate function of this cerebrospinal axis is that of reflex action, the same sort of reflex action that is observed in the lowest forms of life. The elaboration of this simple reflex function into the highly complex and mysterious phenomena of the mind is too large a question to be discussed at the end of a paper. Suffice it to say that the cord, in the essential nature of its phenomena, is not much inferior, and but little different from that part of it which ultimately becomes the encephalon, the accredited seat of conscious mentalization.

This analysis of the cerebrospinal axis, which, for obvious reasons, I have had to make very brief and superficial, shows not only the limits of the cord's dependence and independence, but by placing the function and development of its constituent parts prior in importance to the mere anatomical location and relationship of those parts, it enables the student to grasp more intelligently, and, therefore, to remember more tenaciously those very relationships. The study of the nervous system, as I have endeavored to illustrate in this brief study of that part of it commonly known as the spinal cord, is best conducted by tracing its evolution rather than by merely describing it as it appears in the higher forms of life. Its architecture is better comprehended when observed in the process of building than when it is already builded.

PRE-MEDICAL EDUCATION.*

By STANLEY COULTER, A.M., Ph.D.

Professor of Biology and Director of the Biological Laboratory, Purdue University, Lafayette, Ind.

It is probable that the time will never come when success in the practice of medicine will not depend more upon what our friends down East call "faculty," or what we, in somewhat grosser way, call "commonsense," than upon any course or courses of study open to the medical aspirant. Nothing can take the place of this inborn fitness for practice. Indeed, I very much doubt whether a theoretically perfect course, thoroughly pursued, would make a man a successful physician were he destitute of this. The requirements for a successful practitioner, apart from mere intellectual aptitude and professional skill, are so exacting that were they more fully appreciated the number of matriculants in medical colleges would be greatly reduced. The courage to try the gravest issues, the coolness in emergencies, the skill in separating the causal from the sequential in conflicting symptoms, the tact in calling into play the vital resources of the patient in critical cases—all these are a part of the mental furniture of the successful practitioner and a part of his equipment which shows anticipatory evidence before the pro-

fessional school is entered. No one lacking in these or manifold other qualities which might be named should be encouraged to enter upon the study of medicine.

Our complex civilization is making the interrelation of men so close that to-day problems overlap which were formerly considered sharply distinct. The problem of education is no longer solely in the hands of professional teachers, but the results of teaching, touching as they do upon efficiency in various lines of effort, make the problem one belonging to all branches of work in which trained intellects are a factor in success. So the engineer demands schools especially adapted for the training of engineers, and from the shops and offices of the various great industries comes the statement of what the courses offered should contain. It is so in agriculture, it is so in theology, it should be so in medicine. Up to the present time the attention of the medical fraternity has been turned to the medical school itself; it should be turned, in some degree at least, to the courses preceding the professional school. Holmes was fairly near the mark when he said that properly to educate a man you must begin with his grandparents. Certainly the course in medicine in the professional school would have much greater significance, much fuller meaning, and an infinitely greater value to the student if it were preceded by a wisely planned, thoroughly executed preparatory course in which careful and prolonged training was given in subjects strictly fundamental to those of the medical college.

There might have been a time when a two or three years' course, one-half of which was devoted to chemistry and other elementary, or better, preparatory studies would meet the demand for medical training, but that time is not the present. The tremendous outreaches in surgery and in general practice have so marvelously broadened the field, that such training, with the present outlook, seems plainly almost grotesquely, inadequate. The cry that this is an age of specialization has in it something of justification if we look at the world's workers, but when we look at the schools we find a different side of the shield. The old, even the medieval, has been retained and the new, as it has been developed, has been injected until educational courses are distended to the point of bursting, and the pupil's are given a smattering of an infinite variety of things, a mastery of nothing. In education, save in a few of the larger colleges and universities, this is far from a time of specialization.

It is to prevent this enormous dissipation of energy, to concentrate effort upon a few lines of work definitely and evidently connected with medicine, that I have urged the establishment of pre-medical courses. That such courses are efficient, experience and the testimony of medical faculties bear witness. In nearly all of the larger institutions such courses are now offered, and reports from widely scattered professional schools give evidence of their high value. In 1895, such courses were established independently at the University of Wisconsin and at Purdue, both gaining an immediate and hearty recognition. Since that time other institutions have established such courses where the number of students seemed to justify the necessary increase in the instructional force. The main problem in such courses at present is to make such a perfect articulation between college and professional school, that useless repetition of work may be avoided.

Considering the "raw material" with which the medical colleges have to deal, they are doing marvelously effective work, but they should receive better raw material. Indeed, the time is not far distant when all the leading medical colleges will demand some part, at least, of a college course as a prerequisite for admission. The opinion is unanimous with medical educators that the great defect among medical students is the lack of a thorough preparation for the study of medicine; such an education as can only be obtained in a well-equipped college or university. To quote from a recent circular issued by a prominent medical college: "The student who enters the profession of medicine without this training is seriously handicapped at the very points where he will find it most difficult to make up this deficiency in later years." Such facts should be brought to the attention of every student who intends to become a physician, and while this may be done by the teachers in the university or college, it can be done far more directly and efficiently by the practising physician to whom the ambitious aspirant goes for advice.

"It is of equal importance," indeed it is axiomatic "that the time spent by the student in his college course should be expended to the best advantage in acquiring a knowledge of those facts and a technical skill in those branches which are directly fundamental to medicine. These subjects are quite as useful as any others for the purpose of mental training, and may constitute a considerable part of the college course, without any sacrifice of that general culture which is its fundamental and essential purpose." I quote from the same circular.

To the thinking mind there is nothing so wonderful in these years of splendid achievements as the marvelous advances in operative surgery and the practice of medicine. No profession has so quickly laid hold upon the discoveries of science and no other has so greatly enriched science. So rapidly have new applications of science and new discoveries followed each other that the mind is bewildered at the vision of the possibilities that open before the earnest workers in medicine and surgery. The causal relations existing between public health and public prosperity, between health of body and intellectual possibilities and even of spiritual aspiration, are too patent for discussion. More and more clearly are those relations being recognized by the public and the closer this recognition the more imperative are the demands made upon the medical profession. The physician and surgeon stand in an entirely different relation to their fellows since empiricism has been replaced by science. In view of this new relation, the world is demanding, and demanding of right that those who are clothed with the dignities of the title "Doctor in Medicine" shall have a training commensurate with the high responsibilities which rest upon them.

The extension of courses of study in all medical colleges of the first class, accompanied by an increase both in extent and content of entrance requirements, is an admission of both the imperativeness and justice of this demand. At first thought this course would seem to meet the necessities of the case, but after all does not this solution leave out of consideration certain very important factors which of right enter into the problem? At the same time that professional schools are raising their entrance requirements, colleges and universities are engaged in the like pleasing occupation and even high schools have in a measure caught the infection. How does it all work out? Twelve years in the secondary school's; four years in the college; four years in the professional school. Twenty years of school life! The boy entering school at six, who is never sick, who never fails in his promotions, is able to enter the medical profession at twenty-six. I recognize the fact that time spent in preparation is never lost time, but I

seriously question if much of the work of these long years is preparatory work in any honest use of the term. Indeed, I am far from certain if the most wholesale robbery of our age is not the robbery of time perpetrated upon the youth of the land under the name of education.

When I consider also that these later years of training in university and professional school are years of constantly increasing expense, I am confronted with the question—are we not shutting the door of opportunity in the face of those who have neither time nor means to spend twenty years in study before beginning their life work? Between school and college, between college and professional school, there are great spaces of lost time resulting from an imperfect co-ordination of educational effort. It is because of this that I advocate so ardently that provision be made in colleges and universities for special pre-medical courses.

As the subject presents itself, six or seven years of preparation following the high school seem essential for a course leading to the Doctorate in Medicine. Three or four of these might advantageously be spent in the college and lead to the baccalaureate degree, and three in the medical college. The latter should be a strictly professional school, not loading its schedule with the great blocks of strictly preparatory work which now so largely fill the first year. I have no sympathy with the view that a college diploma should give advanced standing or even admit to a high-grade medical college. There are diplomas and diplomas, and in these days of group studies the diploma may stand for anything or nothing. The diploma carrying with it the entrance privilege to a medical college, should stand for specific work, done in a specific way, with a specific purpose in view.

In such a course two things should be always kept in mind: First, that it should rest upon a broad and solid foundation of what are sometimes strangely called purely cultural studies. The physician of to-day, if he achieve the highest success, must be a man of broad vision, with a clear perception of relations and with a knowledge of language sufficient to bring him into intelligent touch with the workers and the work of his own and other lands. Second, that in the presentation of the scientific subjects, such as might perhaps be called strictly fundamental to a course in medicine the result of training should be not so much an accumulation of facts as an attitude of mind in the presence of facts.

Certain subjects now taught in medical colleges might be taught fully as well, if not better, in the university, and such subjects should be insisted upon as entrance requirements by the medical school. Such subjects are physics, botany, zoology, chemistry, bacteriology, together with a considerable amount of work in physiology and comparative anatomy and dissection. I am far from saying that any course in these subjects should receive recognition, but if the medical faculties will state definitely just what chemistry or bacteriology or physiology they desire, the college and university will be found gladly acceding to the demands. In addition to the actual knowledge which these courses give, it will be found that the years of practice in various laboratories, the ability to take lectures intelligently, the familiarity with the general principles and terminology of the subjects which in the hands of the medical faculty are given a strictly technical application, fit the student in an exceptional way for his professional course. Such a pre-medical course should require all of the general subjects usually considered requisite for the bachelor's degree, especial stress, perhaps, being placed upon the modern languages. In the courses at Purdue University a minimum of three years' work in German or French is required, with provision by election for additional time. Students in such courses should also be required to take at least one year of work in physics, general chemistry, and biology, the work in each subject involving much laboratory practice. Upon such a foundation alone can be safely laid the courses more directly preparatory to the medical school. After such preparation the chemistry may be made to include almost all of that subject now required in the medical college and the work could be given with an attention to detail and an amount of personal supervision impossible to the professional school. In the subjects related to biology the technique so essential to successful work in histology, embryology, and bacteriology can be given in the smaller sections of the university with a thoroughness manifestly impossible in the large classes of the medical college. These subjects underlie modern surgery and medicine in such a way as to make a thorough training in them absolutely essential to the highest success in the professional school.

I would very much like at this point to explain in detail the character and extent of the work done in a high-grade pre-medical course. I can, however, because of time limitation, but call your attention to the course given at Purdue, as shown by these slips, which may be taken as a type, and without comment ask that you believe it to be honestly and closely administered.*

Purpose of the Pre-Medical Course.—The pre-medical course of Purdue University is arranged to meet a three-fold demand:

1. To furnish a broad and liberal education.

2. To give special and extended training in those subjects which underlie the strictly professional studies of the medical school.

3. By this co-relation of work to shorten the time required to obtain the university and professional degrees.

The graduates of Purdue who have completed this course are admitted to the second year of all first-class medical schools, thus saving a full year. That the other purposes of the course are secured is best shown by the synopsis of the course given in the following paragraphs:

The preliminary work required of students entering this course is that of the freshman and sophomore years of the general course, including mathematics, English literature, history, three years of either German or French, and one year each in general chemistry, biology, and physics. Additional general subjects taken are those required of the junior and senior years of the general course, including psychology, literature and history, geology, and German or French.

Special Pre-Medical Studies.—The special work of this course may be summarized as follows:

Quantitative chemical analysis, lectures (37 hours) and laboratory (222 hours).

Organic chemistry, lectures (52 hours) and organic preparations (108 hours).

Physiological chemistry, lectures (18 hours); physiological chemistry and urine analysis (102 hours).

Microscopical technique, lectures (15 hours); laboratory (105 hours).

Normal and pathological histology, lectures (46 hours); laboratory (140 hours).

Vertebrate anatomy and dissection, recitation (74 hours); laboratory (222 hours).

Embryology, lectures and laboratory (88 hours).

* By vote of the society this outline was made a part of the paper, and is hereby inserted

Bacteriology, lectures (37 hours); laboratory (222 hours).

Elective.—Technical chemical analysis, eight hours weekly through the year.

Animal physiology, lectures (37 hours); laboratory (150 hours).
